PREFACE TO THE SECOND EDITION.

MANY changes and additions have been made in the present edition, both as regards the matter and arrangement of the chapters, whilst a considerable number of new sections has been added. These changes and additions, I hope, have removed many of the defects and deficiencies of the previous edition. The main objects which I have kept in view have been to maintain the practical character of the book, and to keep it within a reasonable compass.

Mr. W. H. Jessop has revised his chapter on "Ophthalmic Operations," Dr. C. Hubert Roberts has almost entirely re-written the chapter on "Operations on the Female Genital Organs," and Mr. James Berry has also criticised and made several suggestions concerning the chapter on "Operations upon the Thyroid Gland."

I am indebted to Mr. Alex. Tweedie for many suggestions and much help in revision, to Messrs. A. T. Compton and Percival Yetts for a number of drawings from which the new illustrations were made, and to many teachers of operative surgery who have written to me and pointed out errors or deficiencies.

37 WIMPOLE STREET, W.,

March 1904.

PREFACE TO THE FIRST EDITION.

THIS book has been written with the object of serving as a text-book for the classes held in the Operative Surgery Department of St. Bartholomew's Hospital.

In order to make it a complete handbook for the use of students, a description of many operations which cannot readily be performed on the dead subject has been added.

Previous to the description of an operation, or a group of allied operations, a short account of the main indications for the performance of the operation or operations under discussion is given. This, in my opinion, is an advantage, especially to junior students who are doing a course of Operative Surgery for the first time.

The order in which the different operations have been described may seem peculiar. It is that which is adopted in the practical courses at St. Bartholomew's Hospital, and which has been found to be the most useful, when, as is generally the case in England, only a small amount of material is available for carrying out a course of Operative Surgery on the dead subject.

Most of the illustrations have been prepared specially for this work; where they have been borrowed from other works, the origin has in every case been given.

The illustrations of instruments are taken from blocks kindly lent to me by Messrs. Arnold & Sons, except Figs. 136, 139, 140, 141, 448, and 450, which are from blocks lent by Messrs. Down Brothers.

I take this opportunity of thanking those friends who have helped me in the preparation of the book, especially Mr. Walter

H. Jessop, for the chapter on "Ophthalmic Operations"; Dr. C. Hubert Roberts, for the sections on "Vaginal Hysterectomy" and "Rupture of the Female Perineum"; my colleagues in the Operative Surgery Department, Mr. D'Arcy Power and Mr. M'Adam Eccles, for many valuable suggestions and corrections; Mr. A. T. Compton and Mr. Arthur Harry Beadles, for the drawings from which the illustrations have been made; Mr. P. G. Harvey and Mr. A. R. Tweedie, for a number of photographs; and Mr. J. S. Sloane, for much help in reading the proofs and making the index.

I also beg to thank all those who have kindly given me permission to use illustrations from their works.

I shall be grateful for suggestions and corrections from those who may use the book.

H. J. WARING.

LONDON, *January* 1898.

CONTENTS.

CHAPTER I.

INTRODUCTORY.

	PAGE
Causes of Wound Infection—Sources of Wound Infection	1

CHAPTER II.

PRELIMINARY AND GENERAL CONSIDERATIONS.

Selection of Instruments—Sterilisation of Instruments—Sterilisation of Operation Gowns, Aprons, Towels, Dressings, Gauze, Wool, and Pads—Selection and Sterilisation of Ligature and Suture Material—Sterilisation of Silk—Sterilisation of Catgut—Kangaroo and Wallaby Tendons—Cotton Thread—Cleansing, Disinfection, and Sterilisation of the Hands and Forearms of the Operator, Assistant, and Nurse—Rubber Gloves—Preparation of the Skin of the Patient—Operation Room or Theatre—Solutions—An Improvised Operation Room—Clothing of Surgeon and Assistant—Preparation of Patient for Anæsthesia	4
--	---

CHAPTER III.

PRELIMINARY AND GENERAL CONSIDERATIONS (*continued*).

Position of Patient, Operator, and Assistants—Procedure immediately before Operation—Actual Operation—Methods of Holding a Knife—Arrest of Hæmorrhage—Closure of Wound—Needles, Sutures, and Knots—Introduction of Drainage Tubes—Application of Dressings—After-Treatment	29
--	----

CHAPTER IV.

OPERATIONS UPON THE STOMACH AND INTESTINES.

PAGE

Stages of an Abdominal Operation—Washing out or Irrigation of the Peritoneal Cavity—Methods of Intestinal Suture—Position of Patient, Trendelenberg Position. Gastrostomy, Creation of a Simple Gastric Fistula, Frank's or Albert's Operation, Witzel's Operation. Gastrotomy—Gastrectomy—Pyloroplasty—Pylorectomy—Treatment of Perforated Gastric Ulcer. Operations upon the Small Intestines: Closure of Perforating Wounds—Removal of a Portion of Intestine, by Circular Enterorrhaphy, Mammell's Method, Anastomosis Button, Bone Tube, Bone Bobbin. Lateral Intestinal Anastomosis—Formation of an Artificial Anus—Perforated Duodenal Ulcer—Perforated Typhoid Ulcer. Operations upon the Large Intestine: Removal of the Vermiform Appendix—Suppurative Appendicitis—Excision of the Cæcum—Intussusception—Resection of the Large Intestine—Inguinal Colotomy—Inguinal Colotomy without Sutures—Lumbar Colotomy. Operations upon the Rectum and Anus: Hæmorrhoids—By Ligature, by Excision, by Crushing. Operation for Fistula in Ano: Excision of the Rectum—Perineal Method—Sacral Method—Operation for Imperforate Rectum and Anus	42
--	----

CHAPTER V.

OPERATIONS FOR THE TREATMENT OF HERNIA.

Operation for the Radical Cure of Inguinal Hernia: Bassini's, Kocher's, and Macewen's Operations—Operation for the Radical Cure of Femoral Hernia, Roux's Operation—Operation for the Radical Cure of Umbilical Hernia, Operations for Strangulated Hernia—Inguinal, Femoral, Umbilical, and Obturator Hernie	119
---	-----

CHAPTER VI.

OPERATIONS UPON THE LIVER AND BILIARY SYSTEM.

Upon the Liver: Hepatotomy (for Hydatid Cysts, and for Abscess)—Hepatectomy (Abdominal Operation, Transthoracic Operation)—Ruptures and Wounds of the Liver. Upon the Biliary System: Cholecystotomy, Cholecystendysis, Cholecystectomy, Cholecyst-Enterostomy, Choledochotomy	141
--	-----

CHAPTER VII.

OPERATIONS UPON THE SPLEEN.

	PAGE
Splenectomy—Splenotomy—Treatment of Wounds and Ruptures .	162

CHAPTER VIII.

OPERATIONS UPON THE URINARY SYSTEM.

Operations upon the Kidneys: Nephro-lithotomy, Nephrotomy, Nephrectomy, Lumbar Nephrectomy, Abdominal Nephrectomy, Nephrorraphy. Operations upon the Ureters: Lumbar Operation, Iliac Operation, Trans-peritoneal Operation, Vesical Operation—Ureterotomy—Ureteroplasty—Ureterectomy—Resection of the Ureter—Ureteral Anastomosis—Uretero-ureteral Anastomosis, Van Hook's Method, Bovéc's Method, Poggi's Method—Uretero-vesical Anastomosis, Witzel's Operation, Boldt's Method. Operations upon the Urinary Bladder: Puncture of the Bladder, Litholapaxy, Suprapubic Cystotomy, Lateral Lithotomy or Cystotomy, Median Cystotomy. Treatment of Rupture of the Urinary Bladder: Intra- and Extra-peritoneal Operations. Operations upon the Urethra: External Urethrotomy, Internal Urethrotomy. Treatment of Rupture of the Urethra	168
--	-----

CHAPTER IX.

OPERATIONS UPON THE MALE GENITAL ORGANS.

Operations upon the Penis: Circumcision, Amputation (Partial and Complete). Operations upon the Testicle: Castration, Radical Cure of Hydrocele. Operations upon the Spermatie Cord: for Varicocele, Vasectomy	218
--	-----

CHAPTER X.

OPERATIONS UPON THE FEMALE GENITAL ORGANS.

Operations upon the Vulva: Removal of Urethral Caruncle, Imperforate Hymen, Tumours of the Vulva. Operations upon the Female Perineum: Operation for Partial Rupture, Operation for Complete Rupture. Operations upon the Vagina: Mal-
--

formations. Operations for Vaginal Fistulæ: Vesico-Vaginal Fistula, Urethro-Vaginal Fistula, Uretero-Vaginal Fistula, Vesico-Uterine Fistula, Recto-Vaginal Fistula, Colpo-cliesis; For Tumours of the Vagina; Colporrhaphy, Colpotomy, Vaginal Fixation of a Retroflexed Uterus. Operations upon the Uterus: Dilatation of the Cervix, Curetting, Repair of Lacera- tions of the Cervix, Removal of Mucous Polypi, Removal of Fibrous Polypi, Removal of Intra-uterine Fibroids by the Vagina, Removal of the Cervix Uteri, Vaginal Hysterectomy, Ab- dominal Hysterectomy for Cancer of the Uterus. Operations upon the Ovaries and Uterine Appendages: Ovariectomy, Oöpho- rectomy. Abdominal Operations for Fibromyomata of the Uterus: Abdominal Hysterectomy, Abdominal Myomectomy, Abdominal Enucleation, Abdominal Hysterotomy. Miscel- laneous Operations on Uterus and Uterine Appendages: Hysteropexy, Shortening the Round Ligaments, Cæsarean Section, Porro's operation, Operations for Extra-uterine Gestation	228
--	-----

CHAPTER XI.

OPERATIONS UPON THE RESPIRATORY SYSTEM.

Operations upon the Larynx: Laryngotomy, Thyrotomy, Excision of the Larynx (partial and complete), Intubation of the Larynx. Operations upon the Trachea: Tracheotomy (high and low), Laryngo-Tracheotomy. Operations upon the Lungs: Pneumotomy. Operations upon the Pleuræ: Paracentesis, Incision of the Pleura, Estlander's Operation	268
--	-----

CHAPTER XII.

OPERATIONS UPON THE PERICARDIUM AND HEART.

Paracentesis, Incision — Treatment of Wounds of Heart and Pericardium	288
--	-----

CHAPTER XIII.

OPERATIONS UPON THE ŒSOPHAGUS.

Œsophagotomy—Œsophagostomy—Œsophagectomy—Removal of a Pouch of Œsophagus	291
---	-----

CHAPTER XIV.

OPERATIONS UPON THE THYROID GLAND.

	PAGE
Extirpation of one Lobe—Enucleation of Encapsuled Tumours (Cysts and Adenomata)	295

CHAPTER XV.

OPERATIONS UPON THE TONGUE.

Excision of the entire Tongue : Through the Mouth, after Splitting the Cheek and Division or Resection of a Portion of the Lower Jaw—Through an Incision in the Submaxillary Region : Excision of one-half of the Tongue through the Mouth. Removal of a Wedge-Shaped Portion of the Tongue	300
---	-----

CHAPTER XVI.

OPERATIONS UPON THE CRANIUM.

Trephining : For Fracture of the Skull, for Extradural Abscess or Hæmorrhage, for Cerebral Tumour or Cyst, for Cerebral Abscess, for Cerebellar Tumour or Cyst, for Cerebellar Abscess, Tapping and Drainage of the Lateral Ventricle, Removal of Foreign Bodies, for Epilepsy—Temporary Resection of the Skull—Craniectomy	311
---	-----

CHAPTER XVII.

OPERATIONS UPON THE SPINAL COLUMN AND
SPINAL CORD.

Laminectomy — Operations for Spina Bifida : By Injection, by Excision—Operations for Caries of the Bodies of the Vertebrae—Lumbar Puncture of Spinal Canal	335
--	-----

CHAPTER XVIII.

OPERATIONS UPON THE NOSE AND ITS ACCESSORY
CAVITIES.

Removal of Nasal Polypi—Rectification of Deviated Nasal Septum—Plugging the Nares—Passage of a Eustachian Catheter—	
---	--

	PAGE
Removal of Naso-Pharyngeal Polypi—Removal of Adenoid Growths—Exploration of Frontal Sinus—Exploration of Antrum of Highmore	341

CHAPTER XIX.

OPERATIONS ON THE EAR.

Extraction of Foreign Bodies—Removal of Growths from the External Auditory Meatus: Polypi, Exostoses—Incision of Membrana Tympani—Exploration of Mastoid Antrum and Cells—Stacke's Operation	356
--	-----

CHAPTER XX.

OPERATIONS ON THE TONSILS.

Incision of a Tonsillar Abscess—Removal of the Tonsil: Through the Mouth, through the Neck	363
--	-----

CHAPTER XXI.

THE LIGATURE OF ARTERIES.

Indications for Operation—Instruments—General Method of Operating—Exposure and Ligature of Individual Arteries	367
--	-----

CHAPTER XXII.

OPERATIONS UPON VEINS.

General Considerations—Exposure of Lateral Sinus—Ligature of Internal Jugular Vein—Operation for Varicose Veins—Venesection—Injection of Saline Fluids—Transfusion	425
--	-----

CHAPTER XXIII.

OPERATIONS UPON THE NERVES.

Suture of a Divided Nerve (Primary, Secondary)—Nerve-Stretching—Division of a Nerve—Excision of a Portion of a Nerve—Excision of Nerve Ganglia—Exposure of Individual Nerves—Removal of Meckel's Ganglion—Removal of the Gasserian Ganglion	433
---	-----

CHAPTER XXIV.

OPERATIONS ON TENDONS, MUSCLES, LIGAMENTS, AND
APONEUROSSES.

	PAGE
The Subcutaneous Method—The Open Method. Special Operations : Division of the Plantar Fascia, Division of the Palmar Fascia, Suture of Divided Tendons, Lengthening of Tendons	455

CHAPTER XXV.

OPERATIONS ON THE BONES.

Osteotomy—Operations for Fractures—Excision of Bones	467
--	-----

CHAPTER XXVI.

EXCISION OF ARTICULATIONS.

Methods of Operation—Indications for Operation—Excision of indi- vidual Joints	498
---	-----

CHAPTER XXVII.

AMPUTATIONS.

General Considerations—Indications for Amputation—Points to which Particular Attention should be paid in Amputations— Methods of Amputation and Disarticulation—Modes of Fashion- ing Flaps—Amputations in the Upper Extremity—Amputa- tions in the Lower Extremity	525
---	-----

CHAPTER XXVIII.

OPERATIONS UPON THE MAMMARY GLAND.

Operation for Mammary Abscess—Removal of Localised Non- Malignant Growths—Removal of the Breast : Without Removal of the Lymphatic Glands from the Axilla ; with Removal of the Lymphatic Glands from the Axilla	599
---	-----

CHAPTER XXIX.

PLASTIC OPERATIONS.

	PAGE
Hare Lip : Single and Double—Cleft Palate : Of Soft Palate, and of Both Soft and Hard Palate. Operation for Extroversion of the Urinary Bladder—Operation for Epispadias—Operation for Hypospadias. Skin Grafting: By Ordinary Method, by Thiersch's Method	611

CHAPTER XXX.

OPHTHALMIC OPERATIONS.

General Considerations—Slitting up the Canaliculus—Passage of Lachrymal Probe—Advancement of a Muscle—Paracentesis—Iridectomy—Sclerotomy—Extraction—Discission—Excision .	633
---	-----

MANUAL OF OPERATIVE
SURGERY.

MANUAL OF OPERATIVE SURGERY.

CHAPTER I.

INTRODUCTORY.

THE present Manual of Operative Surgery has for its object the consideration and description of the various surgical operations which may be performed on the human organism, for the alleviation or radical cure of those malformations, diseases, or injuries amenable to direct surgical interference.

It is necessary, however, in order to ensure as far as possible a satisfactory and successful result to all justifiable and advisable surgical operations, that the operator should be thoroughly familiar and acquainted with all the minute details of the modern technique of "prevention of wound infection."

Causes of wound infection.—Bacteriology has conclusively shown that all inflammatory processes in connection with and complications of recent wounds are caused by the presence of pathogenic micro-organisms, together with the products of their vital activity in the actual wounds themselves. The pathogenic micro-organisms which give rise to the development of the above-mentioned complications are not confined to one variety. Most cases of wound inflammation or suppuration are due to an infection with one or other, or sometimes more than one, member of the group of pyogenic bacteria. Of this group, *Staphylococcus pyogenes aureus* and *albus* and *Streptococcus pyogenes* are most commonly found; whilst *Bacillus coli communis*, *B. pyogenes faecidus* and *B. pyocyaneus*, and *Staphylococcus pyogenes citreus* are occasionally met with. Examples of pathogenic micro-organisms, which give rise to special forms of wound infection, are tetanus bacillus—the cause of tetanus; anthrax bacillus—the cause of malignant pustule; and *B. tuberculosis*—the cause of tuberculosis. For a detailed discussion of the different varieties

of pathogenic micro-organisms, and the biological, physical, and chemical conditions which favour or retard their growth and multiplication, the student is referred to works upon Surgical Pathology, Bacteriology, and the Principles of Surgery.

The actual causes of inflammation and suppuration in a wound appear to be the toxins or certain other ferment-like bodies which are produced by the growth and metabolism of the different varieties of pathogenic micro-organisms.

When it is admitted that "wound infection" is always the result of the presence of micro-organisms, and when it is known that these micro-organisms live and thrive in certain situations and under certain more or less understood conditions in the animal body or outside, or, on the other hand, die or lose their virulence under certain other conditions, then it is self-evident that a successful surgeon must be thoroughly acquainted with all the various factors which favour the presence and growth of bacteria, so that he may avoid them, as well as those which hinder their growth or destroy them, so that he may employ them when necessary.

In this way alone can he intelligently apply the various practical methods which are available for avoiding contamination; or, when that is impossible, or has already taken place, for destroying or rendering innocuous the different forms of micro-organisms.

Sources of wound infection.—Every substance, material, or part of the operator and his assistants, brought in contact with or close approximation to a recent wound, may be a carrier of pathogenic micro-organisms and the direct cause of "wound infection" and its complications, if they have not previously been rendered surgically clean by a process of sterilisation.

The fertile sources of "wound infection" are, most commonly, insufficient preparation of the skin of the patient within the field of operation; incomplete cleansing and sterilisation of the hands and arms of the operator, assistant, or nurses; inefficient sterilisation of instruments, suture and ligature material, drainage tubes, sponges, or dressings; or contamination of one of these agents, during the performance of the actual operation, by contact with a body or substance which has not previously been made quite sterile.

Bacteriologists have long known that the cavity of the mouth almost invariably contains numbers of pathogenic bacteria, and recent investigations have conclusively demonstrated that much talking in a room increases very considerably the numbers of micro-organisms floating about in the air of the room. From

this it is clear that talking during the performance of operation is to be deprecated, owing to the increased contamination of the atmosphere of the operation room, and also the risk of small particles of saliva, containing pathogenic micro-organisms, falling directly into an open wound.

In the performance of operations in private houses, it is a very essential factor, as regards the success of the procedure, that the room in which the operation is to be performed should be specially prepared and made as clean as possible, or as the circumstances of the individual case will allow.

A good well-equipped and well-planned operation room, fitted with the modern elaborate appliances for ensuring asepsis, is very desirable in the performance of all surgical operations; but in emergency work, work in country districts, or under conditions where a proper operation theatre or room is not immediately available, this is not possible, and the surgeon is obliged to carry out his proceedings with such space, accommodation, and appliances as may be at hand. On this account it is very important that the student ought to be familiar with the best methods for arranging and preparing a room in a private house, so as to transform it into a comparatively satisfactory operating room. It may be urged that this is the work of a trained nurse, and that a surgeon ought not to be expected to superintend or initiate the carrying out of details of this kind. This, however, is a very unjustifiable argument; and it cannot be too strongly impressed on the would-be successful surgeon, that every detail of the preparation of the operation room, the instruments, dressings, ligatures, sponges, etc., and of the preparation of each individual patient, must be supervised, overlooked, and directed by himself.

In the case of incompetent, untrained, or careless assistants and nurses, he must personally superintend or give implicit directions as to the method of carrying out correctly and completely all the technical details.

Complete and efficient disinfection of the hands and forearms of operator and assistants, instruments, sponges, dressings, and the skin of the patient within the field of operation, is the most essential factor in the successful treatment of recent wounds, and hence in the practice of operative surgery.

These important preliminary and general considerations will now be discussed in detail.

CHAPTER II.

PRELIMINARY AND GENERAL CONSIDERATIONS.

Selection of instruments.—Before a surgical operation is commenced, all instruments which may be required during its performance should be selected and rendered sterile. In order to make a selection satisfactorily, it is necessary to review mentally the different stages of the operation, and to decide what instruments are requisite for each stage. Thus, whenever an incision through the skin has to be made, a cutting instrument, such as a scalpel, is requisite; if the proposed wound is to be a deep one, or the anatomical structure upon which it is proposed to operate is not readily exposed, retractors are required; if blood vessels are to be divided, pressure forceps are necessary; and if a bone requires section, a saw of appropriate size and shape, or bone forceps, must be taken. Needles and a needle-holder are also essential when a wound or part of wound has to be closed, and in all cases ligature and suture material of proper thickness must be in readiness.

Modern surgery and the practice of aseptic and antiseptic principles has effected a considerable modification in the manufacture of surgical instruments. Every instrument or appliance should be manufactured in such a manner that there are as few crevices and irregularities as possible, whilst in the case of scissors and forceps they should be so made that the two different blades can be readily separated, one from the other, in order to facilitate cleaning. All mere ornamentation of the handles or other parts of instruments, by engraving or otherwise, should not be allowed; and it should be insisted upon, that all instruments should be as plain and smooth as is consistent with the uses to which they are to be put. Knives, saws, etc., must have metal handles, all instruments with bone, wood, or ivory handles being discarded. It is a great advantage that each instrument should be as light and of such small size as possible, since this renders efficient and ready sterilisation a far simpler matter than is the case with the heavy and often cumbrous instruments which were so

commonly used by the previous generation of surgeons. This remark applies especially to the very long sword-like amputating knives which were always used when the transfixion methods of amputation were in vogue. Now, in the majority of instances, an amputation is carried out with a moderate-sized scalpel with a strong, firm handle. It is not advisable to use knives which are so made that several blades can be fitted to one handle, or are of the so-called "many-bladed" variety.

As a general rule, it may be stated that only a few instruments are required for the performance of any individual operation, assuming that these are selected with care, and the operator is quite familiar with their use. For the convenience of students, I append the following short list of instruments, which comprises what are essential for the majority of surgical operations. When an operation is being described in the later parts of the book, in which any special instrument or form of surgical appliance is necessary, it will be mentioned under the heading of "Special Instruments"; in other cases, the instruments necessary will be those given below:—

- (a) Knife or scalpel of suitable size and shape.
- (b) Retractors of suitable size and shape.
- (c) Two pairs of dissecting forceps.
- (d) Scissors of suitable size and shape (two pairs may be necessary, straight and curved).
- (e) Hæmostatic forceps (of different size).
- (f) Blunt-pointed curved needle on a handle.
- (g) A probe-pointed director.
- (h) Needles of proper size and shape.
- (i) Needle holder.
- (k) Ligature and suture material.

The student of surgery, from the commencement of his career, ought to accustom himself to use as few instruments as possible during the performance of an operation, and also should make himself thoroughly familiar with the uses to which any ordinary instrument can be put.

Sterilisation of instruments.—During the evolution of surgery many different methods have been practised for the disinfection of surgical instruments. Some of these were dependent upon the employment of chemical agents, others upon the use of some form of heat. Now, it is almost universally admitted that the only satisfactory method of sterilisation of instruments which can be readily employed, is by "boiling in water which contains 1 per cent. of carbonate of soda." The addition of carbonate of soda is necessary, since boiling steel instruments in water rusts them

and thus renders them comparatively useless, especially those which have a sharp or cutting edge. This blunting of sharp and cutting edges is almost entirely obviated by adding to each litre of water a tablespoonful of crystallised carbonate of soda. Ordinary washing soda serves the purpose perfectly well. Experiments have shown that the addition of carbonate of soda intensifies the sterilising action of boiling water. A 1 per cent. solution appears to be the most effective. It will thus be seen that the agents for efficiently sterilising surgical instruments are

FIG. 1.—Steriliser for instruments, ligatures, etc.

(a) Steriliser.

(b) Removable tray.

(c) Gas burner. (This can be replaced by a spirit lamp.)

always at hand. All that is necessary is water, fire, carbonate of soda (common washing soda), and a metallic vessel of sufficient size to hold the instruments. When sterilising cutting instruments, it is an advantage to place the instruments in the solution only after it has been raised to the boiling point; immersion in a boiling 1 per cent. solution of carbonate of soda in water, for from five to ten minutes, efficiently and completely sterilises all ordinary surgical instruments and appliances.

An instrument, the **steriliser**, of the form and shape shown in Fig. 1, is a very useful one for ordinary surgical practice. It con-

sists of an oblong metallic vessel with a closely fitting lid, supported on four detachable supports. The interior is fitted with a metallic tray, which has a handle for lifting, a rack for holding scalpels, hernia needles, etc., and a compartment for ligature reels. It can be heated either by a gas burner or spirit lamp. The advantage of having the supports detachable is that they can be taken off and the entire steriliser readily packed away in a moderate-sized operation bag. For hospital purposes, and whenever a specially fitted operation theatre is available, an enlarged form of steriliser is convenient. Fig. 2 illustrates a much used form.

Rubber and glass drainage tubes, glass syringes, and similar

FIG. 2.—Large steriliser for instruments.

surgical appliances are disinfected and made sterile by boiling in a solution of carbonate of soda, such as has been described.

Selection and sterilisation of sponges.—Marine sponges are in many respects suitable substances for removing blood, debris, lotion, etc., from a wound, during the performance of a surgical operation. An objection to their use is the difficulty which is experienced in making them sterile. Boiling in water or a solution of carbonate of soda destroys their texture and makes them rotten. On this account other measures have to be adopted to prepare them for use. Fresh sponges of suitable size and shape and of a fine texture are selected, and thoroughly washed in a stream

of water, in order to remove the particles of sand which are generally found to be present in them. This substance is often added in order to increase the weight, and so enhance their *commercial* value. When they contain small particles of coral or shell they must be soaked for twenty-four hours or more in a 2 per cent. solution of hydrochloric acid. This reagent dissolves the calcareous particles, and after this has been done they are washed in a stream of water, so as to remove all traces of acid. Next, the sponges are thoroughly washed in hot water (105° F.) and soft soap (potash soap), and then in water with a mixture of soft soap and turpentine. By these means all dirt, particles of sand, coral, or shell, and fat or grease, are removed. The sponges are now washed in warm water, so as

FIG. 3.—Glass jar for sponges. Cover is ground to fit outside.

to remove the soap, and then placed in a closely covered glass jar containing a strong solution of formalin. In this they are allowed to remain for forty-eight to sixty hours, then they are removed and washed in water which has been sterilised by boiling. They are finally placed in a glass jar containing a solution of carbolic acid, 1 in 20. The lid or cover of this jar ought to be ground so as to fit on the outer side, and not closed with a stopper, as in ordinary glass jars. Fig. 3 is an illustration of the form of jar most suitable for surgical work. No dirt can collect and fall in the jar on removal of the cover. They are kept in this until they are required for use. They are then taken out of the

glass jar, the carbolic solution expressed from them, and placed in the bowl which contains the antiseptic or aseptic lotion which is to be used during the operation. If the sponges are kept for any considerable period before being used (and after being prepared), it is necessary to renew the solution of carbolic acid about every ten days or fortnight. This method of sterilisation may be tabulated thus—

- (a) Wash in water to remove sand and solids.
- (b) Soak in solution of 2 per cent. HCl, if requisite.
- (c) Wash in water and soft soap.
- (d) Wash in hot water and mixture of soft soap and turpentine.
- (e) Wash again in hot water.
- (f) Soak in formalin forty-eight hours.

(g) Wash in sterilised water, and place in carbolic acid, 5 per cent. solution, until wanted.

I have used this method for some time, and have found it to be quite safe and efficient. If the sponges are left too long in strong formalin they become rather hard, and develop a tendency to brittleness. Experiments made by taking cultures from sponges so prepared have always shown them to be sterile.

Another method of preparing marine sponges, so as to make them aseptic, is the following :—The sponges are first thoroughly beaten and washed, and, if new, soaked for twenty-four hours in a 2 per cent. solution of hydrochloric acid. They are again washed in water, then placed in a hot solution of carbonate of soda (a teaspoonful to a pint) for half an hour, and again washed in warm sterilised water. Next, they are placed in a watery solution of sulphurous acid (1 in 3), and allowed to remain there for twelve hours. Finally, they are washed in warm sterilised water, to remove all traces of sulphurous acid, and placed in a glass jar containing a 5 per cent. solution of carbolic acid, in which they remain until they are required for use.

This method has been used with great success for some time in the operating theatres of St. Bartholomew's Hospital.

When marine sponges have been used, immediately after completion of the operation they should be placed in a hot solution of carbonate of soda. Then they are thoroughly washed with soft soap and water, in order to remove all blood, *débris*, etc., and finally again prepared by one of the two methods detailed above.

Sponges, "swabs" or "tampons" of cotton wool, gauze, or lint.—Many substances, other than marine sponges, are used for removing blood, *débris*, and lotions from operation wounds. The most important of these are gauze, cotton wool, wood wool, and ordinary lint. All these can be readily sterilised in the steam steriliser, which is described in connection with the disinfection and sterilisation of dressings, towels, operation gowns, etc. When they have been soiled during an operation they are thrown away. Each "swab," tampon, or compress of cotton wool or wood wool should be enclosed in a piece of gauze. This prevents adhesion of loose particles to the tissues. When abscesses or other suppurative affections are being treated,

FIG. 4.—Cellular cloth pad.

10 PRELIMINARY AND GENERAL CONSIDERATIONS.

“sponges” made of cotton wool are the best, as they are cheap, efficient, and can be at once thrown away. In aseptic operations, also, sponges of cotton wool enclosed in gauze, prepared by the method of sterilisation described below, will be found to be the

most satisfactory. In operations upon the contents of the abdomen, marine sponges are usually advisable; then it is necessary to have four round sponges and two flat ones at hand. The flat sponges may be replaced by cotton pads, the material being woven in a cellular manner (Fig. 4). These “pads” are

especially useful in packing away coils of intestine, which impede the operator and obscure the field of the operation.

Sterilisation of operation gowns, aprons, towels, dressings, gauze, wool, and pads.—Disinfection and efficient sterilisation of operation gowns, towels, cotton wool, gauze, pads, and aprons, can most readily and effectually be carried out by submitting them to the action of moist heat. The appliance which is most useful for the purpose, and by practice has been found to be thoroughly reliable, is the "steam steriliser," depicted in Figs. 5 and 6. It is a modification of that designed by Lautenschlager. It consists of two metallic cylinders, usually copper, one within the other, of such sizes that there is a considerable space between them. This space forms the water chamber or boiler, and is bounded externally by a covering of metal and asbestos. A solid metal cover closes in the top, and is fitted tightly by rubber packing and screws.

The inner chamber is the sterilising one, and in it are placed the "kettles" (Fig. 7) containing the articles or substances it is wished to sterilise. Heat is produced by the employment of a Bunsen burner, or a small gas stove placed underneath the boiler.

FIG. 7.—"Kettles" for steam steriliser.

Openings are placed in the upper part of the metal cylinder, which allow the steam generated in the boiler below to pass into the inner sterilising chamber from the space between the two cylinders. The used steam escapes by a pipe below, and it is conducted through a coil of metal tubing placed in a bucket of water, where it is condensed.

In order to efficiently sterilise dressings, operation gowns, etc., it is necessary that they should be submitted to a temperature of at least 100°C . in the steriliser for not less than half an hour.

This appliance can be obtained in various sizes—large for hospital purposes, and medium or small for the use of a surgeon in private practice. Every steriliser which is intended for private use ought to be large enough to contain two kettles, each of which can be hermetically closed after sterilisation. One of these kettles contains operation gown, towels, wool, gauze, and dressings, and the other operation bowls. By the

use of a suitably designed apparatus of this kind all the appliances for an ordinary surgical operation can be sterilised before going to the place of operation.

It is important that towels, operation gowns, etc., should not be folded too tightly before placing them in the steriliser, otherwise there is difficulty in ensuring that the interior of everything is made absolutely sterile. The technical details, which are of importance in working the steam steriliser, are explained in the description of the steriliser and its "kettles" (Figs. 5, 6, and 7).

Another method of sterilisation of towels, etc., is by soaking in a solution of carbolic acid, usually 2 per cent. This is easy of application, but is extremely inefficient; hence it is not recommended. In emergency work, when it is impossible to obtain the use of a steam steriliser, towels may be soaked in a solution of biniodide of mercury solution, 1 in 1000, before being used for protecting an operation wound and its surroundings from being contaminated.

Selection and sterilisation of ligature and suture material.

—Substances which are suitable for use as ligature and suture material may be divided into two classes—(a) Those which are readily absorbable by animal tissues, and (b) those which are not absorbable. To the former group belong the different preparations of "catgut" and animal tendons, and to the latter, silk, silkworm or salmon gut, horse hair, and silver wire. For securing blood vessels, and all forms of buried ligatures and sutures, an absorbable material is theoretically advisable, if the following requirements can be fulfilled:—That the material can be readily and efficiently made *aseptic*, and that it shall not be *absorbed* before the tissues it holds together have had time to firmly unite, or, in the case of blood vessels, until the lumen has been permanently occluded. Catgut, properly prepared and of a thickness suitable for the individual case, can be made to fulfil all these requirements; but it presents more difficulties and requires greater care in its preparation and use than some of the non-absorbable ligature materials, such as silk. On this account silk has, to a considerable extent, replaced the use of catgut. In fact, many surgeons have entirely given up the use of catgut, on account of the difficulties experienced in making certain of its sterility. I do not think, however, that the use of "catgut" should be given up, as there are many instances in which it presents distinct advantages over silk. In practice the following rules, as regards the employment of "absorbable" and "non-absorbable" ligatures and sutures, will be found useful.

1. Sterilised catgut should be used for the ligature of blood

vessels and for buried sutures, in all operations where the area of operation is already septic.

2. Sterilised catgut should be used for the ligature of blood vessels and for buried sutures, whenever the tissues involved are the seat of frequent or extensive movements.

3. Sterilised silk of suitable thickness may be used for the ligature of blood vessels, and for buried sutures and ligatures, in all operations where the field of operation is aseptic, with the exceptions mentioned in 2 and 5.

4. Silkworm or salmon gut of suitable thickness should be used for the closure of all skin wounds, with one or two exceptions, such as the use of horse hair for the face and fine silver wire in certain cases of cleft palate.

5. Silver wire of suitable thickness should be used for the approximation and fixation of bones, such as in operation for fracture of the patella or the long bones of the limbs.

Sterilisation of silk.—This can most efficiently be carried out by first winding the silk on a glass or metal reel, of the shape shown in Figs. 8 and 9, in which there are numerous perforations in the hollow stem, and then boiling in a 1 per cent. solution of carbonate of soda for twenty to thirty minutes. Many special sterilisers have been designed for this purpose. A small enamelled iron saucepan, however, is the simplest and best. In practice it is often found convenient to sterilise the ligature silk along with the instruments.

FIG. 9.—Metal reel.

FIG. 8.—Glass reel.

Horse hair and salmon gut are easily and effectively sterilised by boiling. They should not be wound on reels; it is sufficient to wrap them up in a long piece of gauze before placing in the steriliser.

Silver wire also is sterilised by boiling in a solution of carbonate of soda, 1 per cent.

Sterilisation of catgut.—Catgut cannot be boiled in a 1 per cent. solution of carbonate of soda in water without being practically destroyed; it loses its extensibility and becomes friable, so that, when any tension is exerted upon it, the strands break. Several other procedures, however, are available for rendering the substance quite sterile. The most efficient are those which are known as the "xylol" and "formalin" methods.

Xylol method.—A special form of steriliser or sterilising tube is necessary. Figs. 10 and 11 are illustrations of the appliances

FIG. 10.—Tube steriliser for preparation of catgut by xylol method.

A. Tube.

B. Metal plate on which catgut is wound.

which are the best for the purpose. The raw catgut is taken and wound round a metal or glass plate or piece of wood, of the shape shown in Fig. 12. The gut should not be wound tightly. Next, the metal plate and catgut are placed in the sterilising tube containing xylol (Fig. 10), the top tightly screwed on, and then the entire tube is placed in an ordinary water or steam steriliser, where it is left for twenty minutes to half an hour. The sterilising tube is then removed from the steriliser, the plate with the catgut removed from the interior of the tube, shaken free of all adherent xylol, and then placed in a glass jar containing a spirit solution of mercury biniodide 1 to 500 (75 parts of methylated

FIG. 11.—Large steriliser for xylol method of preparing catgut.

A. Cover of xylol chamber.

B. Inner chamber containing xylol.

C. Outer chamber containing water or solution of ammonium sulphate.

D. Gas burner.

spirit to 25 of water). In this it is kept until it is required for use.

For hospital purposes, the form of steriliser shown in Fig. 11 is useful. It consists of an ordinary water steriliser, with an inner vessel in which the xylol and catgut are placed. The top of the inner chamber should have a tightly fitting lid, which will prevent any possibility of the contents taking fire. Some surgeons have suggested that the fluid in the water chamber should be a saturated solution of ammonium sulphate in water. This boils at over 120°C ., hence the temperature of the xylol is raised beyond the boiling point of water. (Xylol boils at 148°C .) This, however, is not necessary.

Formalin method.—Commercial raw catgut is taken and wound on a glass, metal, or wood plate, as in the xylol method. It is first washed and brushed with soap and water, and then placed in a 4 per cent. solution of formalin in water. Here it is left for twenty-four to forty-eight hours, then taken out and thoroughly washed in sterilised water, so as to remove the formalin. Next it is boiled in water from fifteen to thirty minutes, fifteen minutes for the finer strands and thirty minutes for the thicker

FIG. 12.—Plate on which catgut is wound.

ones. It is now placed in an alcoholic solution of biniodide of mercury, 1 in 500, and kept until required for use.

Both these methods are quite reliable, and the surgeon can depend upon the material being absolutely sterile when it has been treated thus. Personally I think the xylol method the better, except in the case of fine strands of gut, when the formalin method is the more preferable, since this latter method of preparation makes the gut stronger and more tensile.

Kangaroo and Wallaby tendons.—The tendons of the hind-limbs of the kangaroo and wallaby have been used as absorbable sutures and ligatures. This material is expensive, and in my opinion does not present any advantages over well-prepared catgut. It is, moreover, more difficult to render sterile.

Cotton thread.—Cotton thread has been used as a non-absorbable ligature material. It presents no advantages over silk, and is not so reliable. In emergencies, however, it may be used instead of silk. It is sterilised by boiling in a 1 per cent. solution of carbonate of soda in water.

Cleansing, disinfection, and sterilisation of the hands and forearms of the operator, assistant, and nurse.—There is no doubt that the efficient disinfection of the hands and forearms of the surgeon, assistant, and nurse is one of the most essential factors in the performance of a successful aseptic operation. The following method I have found, by long experience, to be quite efficient and easy of application:—

(a) The finger nails are cut short and all macroscopic particles

FIG. 13.—Metallic nail-cleaner.

of dirt or débris removed from underneath them by the energetic use of a metallic nail-cleaner (Fig. 13).

(b) The skin of the hands and forearms is thoroughly washed and scrubbed with a sterilised flesh brush, for five minutes, in hot water and soap—soft soap or surgical soap being the most effective. (Specially prepared potash soap can be obtained in collapsible tubes or jars. This is the best for the purpose.) The brush, after sterilisation, should be kept in a solution of mercury biniodide, 1 in 1000, or 5 per cent. carbolic lotion, in a glass brush box, of the shape illustrated in Fig. 14.

FIG. 14.—Glass box for brush.

(c) The skin of the hands and forearms is well washed with a mixture of potash soap and turpentine, in order to remove sebaceous material, grease, and fats, from the surface of the skin and the openings of the sebaceous and sweat glands. (Ether, benzine, alcohol, or xylol may be used instead of turpentine. Personally I have found turpentine to be more effective than ether or alcohol.)

(d) Next, after the soap and turpentine have been removed by washing in warm water, the skin of the arms and hands is soaked in or washed with an alcoholic solution of biniodide of mercury, of the strength 1 in 500, for two minutes. (This solution consists of 75 parts methylated spirit, 25 parts water and biniodide of mercury.)

(e) Finally, the hands and forearms are washed with a lotion

consisting of water and biniodide of mercury, 1 in 2000. If some other lotion is being used at the operation, such as normal salt solution or carbolic acid solution, this may be used instead.

It cannot be too strongly impressed upon students and nurses, that efficient disinfection of the skin depends more on energetic mechanical brushing with hot soap and water and turpentine than upon the use of chemical reagents such as biniodide of mercury or carbolic acid.

This method of preparation of the hands and forearms ought to be carried out in all cases, even in those which are known to be septic at the time of operation, otherwise fresh varieties of pathological micro-organisms may be introduced, and erysipelas, tetanus, or other acute infection superimposed upon that already existing.

The "fetish" of simply dipping the hands or even only the fingers into a bowl of carbolic or other lotion, before commencing or taking part in an operation, can best be stigmatised by saying that it is the completely futile proceeding of a non-educated and incompetent surgeon, who ought not to be allowed to perform any operation beyond the opening of a superficial abscess.

Similarly, this habit must be avoided in the case of soiled hands, instruments, etc., during an operation.

Rubber Gloves.—Some surgeons use rubber gloves, which have been sterilised, when operating, in order to avoid infection of the wound from the skin of the operator. The use of these gloves is, however, accompanied by several disadvantages. The surgeon is not able to feel the parts he is operating upon so distinctly, and he is hampered on this account in carrying out any delicate manipulations or dissections. For these reasons I do not recommend their general use. When, however, the surgeon's hands are injured or eczematous, or suppurating cases are being operated upon, then I think the use of rubber gloves presents advantages.

Preparation of the skin of the patient within the field of operation.—On the afternoon of the day previous to operation, the patient has a hot bath, and the skin all over the body is well scrubbed with soap and water. After the bath, the skin of the patient within and around the field of operation is scrubbed with soft soap and hot water and shaved with a razor. Shaving is advisable in most cases, even when there is only a small growth of hair on the part concerned. It is a very efficient method of removing the sodden epithelium of the surface and its contained bacteria. The scrubbing and brushing with hot water and soft soap ought to be continued for five minutes. The skin of ladies

and children, however, usually requires less energy for complete disinfection than that of an artisan, ~~or of a hospital patient who~~ has rarely indulged in the luxury of a bath. Next, the skin is well washed with soap and turpentine or ether, so as to remove any remaining fat or sebaceous material. The area of operation is now for two minutes washed with or soaked in an alcoholic solution of mercury biniodide, 1 in 500, such as is used in disinfection of the hands.

These proceedings having been efficiently carried out, the skin is bathed with a lotion of mercury biniodide, 1 in 2000, and then covered with a layer of sterilised gauze which has been previously soaked in the same lotion. A layer of sterilised wool—either sal alembroth or boracic acid may be used, the latter when the patient has a tender and sensitive skin—is then laid upon the gauze, and this covered with an outside dressing of gauze and jaconet, and the whole bandaged in position. This is left fixed until the time of operation, when it is removed, and the skin again thoroughly washed with the alcoholic solution of mercury biniodide. This should not be done until everything is ready for the performance of the operation, and the patient has been anaesthetised. If there should be any doubt about the efficiency of the preparatory disinfection and sterilisation of the skin within and around the area of operation, the entire process should be gone through in every detail after the patient has been anaesthetised, and before the sterilised towels have been placed in position.

When the skin within the field of operation is the seat of an ulcer, such as in a case of fungating carcinoma of the breast, or of an open sinus, an attempt should be made to sterilise the infected area, and shut it off from the operation wound. This can best be attempted by scraping away with a sharp Volkmann's spoon any granulation tissue which is evident, then cauterising the bare area with the actual cautery, or strong carbolic acid (90 per cent.), and finally covering the part either with a layer of sterilised gauze dipped in collodion, or by several layers of gauze which have been soaked in a lotion, such as mercury biniodide, 1 in 1000. This method of preparation is of course carried out after the patient has been anaesthetised. Ulcerating carcinomatous growths of the breast can often be rendered aseptic by repeated antiseptic fomentation for some days before operation.

In operations of emergency, such as for strangulated hernia, acute intestinal obstruction, or severe injuries, it is generally impossible to carry out in their entirety these preliminary precau-

tions, owing to the necessity for the immediate performance of the operation. The skin, in these cases, in the neighbourhood of the field of the operation is shaved, so as to free it from hair, and then made as aseptic as possible by washing it with soap and hot water, ether, or turpentine, and then with alcoholic biniodide of mercury solution, after the manner already mentioned.

Operation room or theatre.—In all properly equipped hospitals one or more rooms are specially fitted up for operations. It is advisable in each hospital that there should at least be two theatres—one for aseptic cases, and the other for those in which suppuration is known to exist at the time when the operation is performed. When two separate theatres are not available, on each operation day the non-septic cases should be dealt with first and the septic ones afterwards. Then the room is entirely cleaned and sterilised, so as to be ready for aseptic cases on the following day. In practice, however, it will occasionally happen that a septic case is operated upon before the aseptic ones are finished, owing to an error in diagnosis. When this occurs, great care must be taken to have all appliances and instruments thoroughly sterilised before proceeding with the aseptic cases. Often it may be advisable to defer the remaining operations until the following day.

An operation theatre should be of convenient size, and have the walls, floor, and roof made of material which can be readily cleaned by mechanical means, and which does not readily absorb any form of liquids. The floor should be of cement or concrete, and the walls and part of the roof which is not occupied by windows, of the same material, or covered with glazed tiles or sheets of glass. The lines of junction of the floor and side walls, the junctions of the side walls themselves, and their union with the roof, should all have rounded corners and angles, so as to avoid any crevices or spaces which may readily become the lodging-places of dust, bacteria, etc.

LIGHT.—Every operation theatre should be placed on the top of the building, and be so arranged that there are both side windows and also a top light or window in the roof. This skylight should be fixed, and not made to open by cords, pulleys, etc. The side windows may be arranged so as to open for ventilation. Electric light should be installed and fitted, so that a strong light can be thrown on any part of the patient without interfering with the operator or his assistant. Electric plugs should also be fitted, which will serve for supplying current to a cautery or an electric motor.

VENTILATION.—All draughts must be avoided, doors being

made to fit closely and to open by sliding. The air may be changed by having an electric exhaust fan, for taking the air out, and the inlets so arranged that the incoming air passes through cotton wool, or is warmed and sterilised as by the Plenum system.

DISINFECTION.—This is carried out by washing with a solution of carbonate of soda, and by spraying steam and antiseptics on the entire surfaces of the walls, floor, roof, etc.

FIG. 15.—Washing basin and sink for operation room. The different taps have pedal attachments so that they can be worked by the feet.

WARMING.—This is best effected by the employment of radiant heat, or by warming the incoming current of air.

EQUIPMENT.—Every operation theatre, or series of operation theatres, should have in connection several other rooms, which may serve as dressing room, anaesthetising room, recovery room, sterilising room, instrument room, and bath room and lavatory.

The actual operation room should be fitted up with a proper

operation table, a table for instruments, a table for lotions and sponges, a table for the equipment of the anaesthetist, and a properly arranged sink and washing arrangements. The taps and plugs of the sink and washing basins should have pedal attachments, so that they can be worked by the feet. These washing arrangements are for use during and between operations, and are not intended to be used in the first preparation of the arms and forearms of the surgeon, assistant, and nurse. A proper supply of bowls and trays (Figs. 21, 22, 23) for lotions,

FIG. 16.—Enamelled iron operation table. This table has a “raek” arrangement for placing the patient in “Trendelenberg” position in abdominal and pelvic operations.

sponges, and instruments of different sizes, and one or more large jugs for use during irrigation when necessary, must be provided.

The choice of an operation table is a difficult one. It ought to be strong, capable of being warmed, readily cleaned, and fitted with an arrangement for placing the patient in the “Trendelenberg” position. Fig. 16 is an enameled iron operation table, which possesses most of the requirements of operative surgery. Figs. 17 and 18 are illustrations of tables which are the most suitable for instruments, lotions, etc. The

curved table is for the trays containing instruments and ligatures, and is placed on the side of the operator, the oblong one for bowls containing sponges and lotions, and is on the side of the assistant and nurse.

FIG. 17.—Oblong metal table with glass top and shelf, for bowls, lotion, etc.

They are made of enamelled iron or polished brass and plate glass.

A supply of sterilised water must be at hand, and also materials for making the various antiseptic lotions which are used in the practice of aseptic and antiseptic surgery. Two methods of sterilising water for use in opera-

tion theatres are adopted. One is by boiling in a copper vessel, and the other by the use of a filter, such as those known as Berkefeld or Chamberland (Fig. 19). The former, when carefully

FIG. 18.—Curved metal table with glass top and shelf, for instruments.

looked after, appears to be reliable in providing sterile water. The "ideal" arrangement, however, in my opinion, is to have

FIG. 19.—Berkefeld aseptic filter. An apparatus for supplying sterilised water of regulated temperature for use in surgical operations. It consists of two parts, namely, the copper cylinder J and the Berkefeld filter H. The former contains a copper coil thickly tinned inside; through this coil hot water passes from the hot water supply, and as this is generally too hot for use in surgical operations, it can be tempered by filling the space around with cold water. By passing more or less cold water through the cylinder, and with the aid of the thermometer, the temperature of the water in the coil can be regulated to any required degree of heat.

the water sterilised by boiling, and kept in a reservoir in an adjoining room, and to have a tap or pipe of supply in the actual operation room. Fig. 20 is an illustration of a copper

FIG. 20.—Copper boiler, for use in producing sterilised water.

FIG. 21.—Round bowl (of glass or enameled iron) for sponges or lotions.

boiler which is much used for the preparation of sterilised water in connection with the operation theatres of hospitals.

FIG. 22.—Flat tray (of glass or enameled iron) for instruments.

Every operation theatre ought to be under the direct charge of a trained surgical nurse. There are so many details of cleansing which are more readily understood by a woman than by a man, that it appears to me to be more fitting for this part of the arrangements to be placed under a nurse. A properly trained surgical nurse who understands the technique of modern surgery is indispensable to a successful surgeon. In fact, one feels justified in stating that the success of an aseptic operation depends almost as much upon the nurse as upon the surgeon.

Solutions.—The following solutions are those which are most frequently used and the most useful and efficacious in surgical operations :—

FIG. 23.—“Kidney” shaped bowl (of glass or enameled iron) for use during irrigation, or when opening abscesses, cysts, or other fluid-containing tumours.

1. *Normal salt solution*.—This is made by adding to sterilised water $0\cdot75$ per cent. of sodium chloride. For emergencies a teaspoonful of salt, added to a pint of water, represents, for all practical purposes, the strength of this solution.

2. *Biniodide of mercury*.—This is generally used as a solution having a strength of 1 in 2000 or 1 in 4000. The addition of a small quantity of potassium iodide facilitates the solution of the salt in water.

BINIODIDE OF MERCURY SOLUTION (1 in 2000)—

Biniodide of mercury	. . .	0·5 gm.
Iodide of potassium	1 „
Sterilised water	. . .	1 litre.

BINIODIDE OF MERCURY SOLUTION (1 in 4000)—

Biniodide of mercury	. . .	0·25 gm.
Iodide of potassium	1 „
Sterilised water	. . .	1 litre.

BINIODIDE OF MERCURY SOLUTION (1 in 500)—

Biniodide of mercury	. . .	0·4 gm.
Methylated spirit	. . .	0·75 litre.
Sterilised water	. . .	0·25 „

3. *Perchloride of mercury*.—This reagent is used in solutions having a strength of 1 in 1000, 2000, 3000, or 4000. The salt is not very readily soluble in water, and in order to facilitate this solubility a small quantity of alcohol is added.

PERCHLORIDE OF MERCURY SOLUTION (1 in 1000)—

Perchloride of mercury	. . .	1 gm.
Alcohol	. . .	100 „
Sterilised water	. . .	900 „

Tabloids of biniodide of mercury and perchloride of mercury can be obtained, which, when added to a sufficient quantity of sterilised water, make a solution of the strength required.

When solutions of mercury are used, it must be remembered that metallic instruments ought not to be placed in the perchloride solutions, since they are affected by it. Biniodide of mercury solutions have not this deleterious effect.

4. *Carbolic acid*.—This is usually used as a $2\frac{1}{2}$ or 5 per cent. solution.

CARBOLIC ACID SOLUTION, 5 per cent.—

Carbolic acid	. . .	50 grms.
Glycerin	. . .	50 „
Sterilised water	. . .	1 litre.

CARBOLIC ACID SOLUTION, $2\frac{1}{2}$ per cent.—

Carbolic acid	. . .	25 grms.
Glycerin	. . .	25 „
Sterilised water	. . .	1 litre.

CARBOLIC ACID SOLUTION, 90 per cent. (for use as a caustic)—

Carbolic acid	90 grms.
Sterilised water	10 „

Many other chemical antiseptics are used by different surgeons, such as formalin, lysol, izal, iodoform, iodine, boracic acid, chloride of zinc, creolin, etc. For special purposes many of these are useful, but for general routine surgical work the solutions mentioned above will meet nearly all requirements.

An improvised operation room.—It is often necessary, in emergency work and in private practice, that a surgical operation shall be performed in a private dwelling-house. A room should be selected as an operation room which is well lighted (a top light if possible), and can be well warmed. A little-frequented room of moderate size is the best. The room should, if possible, be prepared the day preceding the operation, and then closed. Curtains, pictures, in many cases carpets, and all unnecessary furniture, must be removed. Every part of the room is well brushed and dusted, so as to remove all dry dust. Next, the floor, walls, windows, and door are washed and scrubbed with a hot solution of washing soda, and then scrubbed with a solution of perchloride of mercury, 1 in 1000. Some recommend that a 5 per cent. solution of carbolic acid should be used instead. Personally, I think the perchloride of mercury solution is the more effective. When the room is prepared on the day previous, disinfection by the formalin method may be employed. It is very efficacious, but requires many preparations for carrying it out.

The danger of infection from micro-organisms floating about in the air may be minimised considerably by steaming the room with a jet of steam. When the room has been prepared, the windows and doors are closed, and it is left until the next day.

As regards an operation table, a strong kitchen table, as narrow as convenient, should be selected, and prepared in the manner described for the room. Arrangements should be made for a supply of boiled water, and also for a fire or stove, where towels and bowls can be sterilised by boiling in a soda solution. Bowls may be sterilised in extreme emergency by placing in them a quantity of methylated spirit, and setting fire to it. This is not a very reliable method, but is readily available and easily applicable.

The trained surgical nurse is of great assistance in the preparation of rooms for an operation. She understands more perfectly than a man many household duties which are neces-

sary for undertaking work of this kind. There is no doubt that in many cases of emergency operations, and operations performed in private dwellings, that the trained nurse performs the most difficult task when she makes all the necessary arrangements and preparations which are essential for the success of the proceeding.

FIG. 24.—Operation gown.

a. View with sleeves rolled up.

b. View with sleeves buttoned around forearm.

Clothing of surgeon and assistant for operation.—During the performance of surgical operations, the surgeon and assistant should divest himself of shirt and collar, and replace them by a shirt of soft woollen material. The advantages of this are, that the surgeon has a comfortable under-garment which will absorb fluids excreted by the skin, and can be easily

sterilised before use. Removal of the collar and stiff white shirt also makes movements more comfortable for the surgeon, and avoids these articles of attire being soiled with blood or contaminated with micro-organisms when dealing with septic and suppurating cases. An operation gown, of the form and shape shown in Fig. 24, which has been sterilised by moist heat in the steam steriliser, should be put on after the hands and forearms have been prepared. The gown should be made to fit the body not too tightly, so as to allow free movements, to extend downwards to the heels, to fit closely to the neck, and to fasten behind. The sleeves should extend a little below the bend of the elbow, and have an arrangement for being fastened.

A good practical rule which may be adopted in surgical operations is, that articles of clothing should not be allowed to extend below the elbow, and that surgeon and assistant and nurse must each wear a sterilised gown made of some variety of woven cotton material. In emergency operations a cotton sheet or large towel may be sterilised and fastened round the operator and assistant.

Preparation of patient for anæsthesia.—An aperient medicine should be given, if possible, on the day preceding the operation, and an enema on the morning of the operation, so as to evacuate the intestines; this is especially necessary before operations on the abdominal portion of the alimentary canal, or upon the rectum. No food should be given by the mouth for three or four hours before the operation is performed. Proper observance of these precautions tends to avoid vomiting during the administration of the anæsthetic, and also involuntary evacuation of the fæces. If these preparations are effectively done, the patient's bowels remain inactive, as regards evacuation of fæces, for several days, a condition which is especially necessary after the performance of many abdominal operations. When the alimentary canal is the seat of operation, it is of great advantage that it should be as empty as possible, so that the possibility of soiling the peritoneum with intestinal contents may be minimised. In many abdominal operations, especially those which involve the pelvic viscera, it is advisable to empty the bladder immediately before or after the commencement of the administration of the anæsthetic. This can be done either by directing the patient to pass water shortly before coming to the operation room, or by passing a catheter when the anæsthetic has been given.

CHAPTER III.

PRELIMINARY AND GENERAL CONSIDERATIONS (Continued).

Position of patient, operator, and assistants.—The patient should be placed in a position that will at once ensure the greatest possible advantage being taken of all available light, afford a complete exposure of the field of operation, and in no way hamper the movements of the operator and his assistant. Care, however, must be taken that the respiration of the patient is not interfered with, and that room is allowed for the administrator of the anæsthetic.

The operator places himself in such a position that he can easily and readily get at the region which is to be operated upon, whilst the assistants are so placed that they can afford the greatest help to the surgeon without impeding his movements.

The assistant or assistants, especially when not well acquainted with the technique of surgical operations, should receive explicit instructions from the surgeon as regards their duties. A good assistant in a surgical operation does what is required of him at the right moment, but otherwise does not interfere with the course of the operation.

Procedure immediately before operation.—1. Coat and collar of surgeon to be removed.

2. Shirt to be taken off and replaced by a short-sleeved woollen one, or sleeves to be turned up and fixed above elbows.

3. Thorough preparation of hands, arms, nails, etc., according to methods already described.

4. Sterilised operation gown (Fig. 24) to be put on.

5. Preliminary dressing on patient to be removed, and field of operation to be again prepared or washed with a solution of mercury biniodide (1 in 500).

6. Hands to be again disinfected if there has been any possible contamination or source of contact with non-sterilised areas or substances.

7. Sterilised towels to be arranged around field of operation, so as to effectively prevent contact with non-sterilised materials.

8. Special instructions, if any are requisite, to be given to assistant and nurse. When these preliminary preparations have been carried out, the actual operation may be commenced, the surgeon first assuring himself that the anæsthetist is ready for him to begin.

FIG. 25.—Scalpel of good shape, with a metal handle.

Actual operation.—Every surgical operation can be conveniently divided into several stages, the number of which varies somewhat according to the class of operation which is being performed. In nearly all cases the first stage is the *skin incision*. This is made with a cutting instrument, usually a scalpel. In some forms of operation, however, such as tenotomy, a special knife called a tenotome is used; or, in amputations, an amputation knife of suitable shape is employed; whilst in those cases in which the skin is not divided, such as the removal of a nasal polypus or the excision of laryngeal growths by the intra-laryngeal method, no knife is necessary, a special form of instrument suitable for the individual operation being made use of. Fig 25 is a representation of a good form of scalpel. This form of knife is recommended for making most skin incisions which are of moderate length, and for carrying out any dissections which may be necessary during the further stages of the operation.

Method of holding a knife.—Several different methods of holding a knife, when performing a surgical operation, are adopted. These may be classified as follows, namely:—

- (a) “Dissecting” position.
- (b) “Fiddle-bow” position.
- (c) “Dinner-knife” position.
- (d) “Grasping” position.

(a) Fig. 26 is an illustration of the manner in which a scalpel ought to be held in the first or “dissecting” position. This is sometimes called the “pen” or “writing” position. This method ought to be adopted in making nearly all incisions

which are not more than 3 or 4 in. in length, and in all cases where any fine or delicate dissection is necessary, such as the

FIG. 26.—“Dissecting” position of holding a knife.

exposure of an artery, nerve, or vein, or when separating any new growth or other pathological formation from its connections with important structures.

FIG. 27.—“Fiddle-bow” position of holding a knife.

(b) Fig. 27 is a representation of a scalpel held in the “fiddle-bow” position.

FIG. 28.—“Dinner-knife” method of holding a knife.

This method of holding a knife is made use of by some surgeons when making skin incisions and rough dissections, but its adoption is not recommended, since the instrument is not

held so firmly as in Fig. 26, and consequently greater risk is incurred, in the performance of a delicate dissection, of doing damage to the adjacent structures.

(c) When it is desired to make a long incision, as in the removal of a large tumour or the formation of the flaps in an amputation, or to separate soft tissues from their connection with bone, as in excision of a joint, the knife should be held in the so-called "dinner-knife" position. This method of holding a knife is shown in Fig. 28.

(d) When it is necessary for the surgeon to make a long sweeping cut, as in performing an amputation by the "circular" method, the knife is usually held in the position shown in Fig. 29. This position is sometimes called the "grasping" position.

FIG. 29.—Amputation knife held in the "grasping" position.

Great care must be taken, when making an incision through the skin and underlying soft tissues, to avoid what is called "tailing" of the incision. By the term "tailing," in operative surgery, is understood making the central part of an incision deeper than either one or both extremities. In order to avoid this, some surgeons advise that the knife should be held in a vertical position at the commencement of the incision, thus making this part of the operation of the nature of a stab. There is a decided objection to this method of commencing an incision. The skin is much tougher and more resistant than the underlying soft tissues, and, owing to this fact, it some-

times happens, when the scalpel is entered in this manner, that the point penetrates much more deeply than is wished, and perforates an important blood vessel, or divides an adjacent nerve trunk. On this account the "vertical" method of commencing an incision is not recommended. It is advised that all ordinary incisions which are of moderate length should be commenced with the knife held as in the position shown in Fig. 28, and that the blade of the instrument should be used for cutting the tissues; as the knife is brought out from the wound, the handle

is raised, so as to make it almost vertical, by which means "tailing" in this part of the wound is avoided. A beginner in operative surgery usually has a tendency to use the point of the knife too much, instead of the blade, whilst making the main part of the incision. The wound is maintained of equal depth for its entire length, until the anatomical structure sought for is laid bare. In order to do this, it is usually necessary to make an occasional extra light stroke with the knife in the upper part

FIG. 30.—Pressure forceps.

of the incision, since there is a tendency to slightly tail this portion of the cut.

The further stages of each operation differ according to the procedure which is being carried out. They will be described in connection with the individual operations.

Arrest of hæmorrhage.—During the performance of every surgical operation which necessitates the division of blood vessels, attention must be paid to the arrest of hæmorrhage.

This is effected by seizing each bleeding point with a pair of

pressure or artery forceps, and then applying a ligature. Figs. 30 and 31 are illustrations of pressure and artery forceps.

FIG. 31.—Artery forceps.

Hæmorrhage from small blood vessels can usually be arrested by seizing the bleeding point with pressure forceps and twisting it. This is called arrest of hæmorrhage by torsion. Occasionally it is desirable to operate by what is called the “bloodless” method. In this case an elastic bandage is wrapped around the affected limb, commencing below, and applied sufficiently tightly to force the blood upwards, and to arrest the circulation in the arteries which supply the part. An elastic tourniquet is then fastened around the limb above the region upon which it is proposed to operate, a strip of lint being placed between the rubber tube and the skin, and the elastic bandage removed. When the operation is completed, this tourniquet is gradually loosened, and all bleeding vessels picked up with pressure or artery forceps and ligatured in the usual manner. Figs. 32 and 33 are illustrations of the rubber bandage and tourniquet which are used for this purpose. The use of the bandage may be dispensed with in many cases, and, instead, the limb may be elevated for a few minutes, and the blood forced towards the trunk by stroking with the hands before the

application of the tourniquet. All hæmorrhage should be carefully arrested before a wound is closed.

Closure of wound.—The final stage of the majority of surgical operations is the closure of the external wound. This is usually effected by the introduction of some form of suture or sutures. The two commonest and most useful methods are the “interrupted” and the “continuous” suture. The instruments which are necessary for this proceeding are needles, a needle-holder, and suture material. Figs. 34, 35, and 36 are illustrations of fully-curved, half-curved, and straight surgical needles. The shape of the needle which ought to be used for closing an in-

FIG. 32.—Rubber bandage for rendering a limb bloodless during an operation.

cision depends upon the depth and accessibility of the wound. In deep wounds, or wounds which are not readily accessible,

FIG. 33.—Elastic tourniquet.

FIG. 34.—Fully-curved needle.

FIG. 35.—Half-curved needle.

FIG. 36.—Straight needle.

curved needles will be found to be most useful, whilst for shallow cuts straight needles will be most convenient. Fig. 37

represents a useful and simple form of needle-holder. The instrument shown in Fig. 38 will occasionally be found to be very

FIG. 37.—Needle-holder suitable for all kinds of surgical needles.

useful in sewing up external wounds. The needle is passed through the tissues, the suture slipped into the slot near the apex, and the needle withdrawn. The use of this form of needle obviates the necessity of threading each suture, and also the

FIG. 38.—Combined needle and needle-holder.

use of a needle-holder. It will be found most useful for closing long incisions.

Closure of an incision by a simple interrupted suture.—

FIG. 39.—Method of introduction of a series of simple "interrupted" sutures. All the sutures have been introduced, but none tied.

The individual sutures are introduced separately at equal distances from each other, and after the manner shown in Fig. 39.

The insertion of a series of interrupted sutures can be facilitated by the assistant placing a blunt hook in each extremity of the wound, and exerting traction in opposite directions so as to render the margins taut.

When all the sutures have been inserted, each one is tied and the ends cut short. Fig. 40 shows the appearance of an

FIG. 40.—Row of simple “interrupted” sutures inserted, tied, and ends cut short.

incision which has been closed by the insertion of a row of simple “interrupted” sutures. This method, in my opinion, is the best for the closure of wounds. When the wound is a deep one, it is advisable to close the deeper parts by the insertion of a tier of “buried” sutures.

Closure of an incision by a continuous suture.—This form of

FIG. 41.—Method of inserting a simple “continuous” suture.

closure of a skin incision is a good one, since by its adoption the margins of the wound can be readily brought into fair apposition and kept there until union has taken place. A little more care, however, is required than when the “interrupted” suture is inserted. Fig. 41 shows the method of inserting a

FIG. 42.—Appearance of an incision when closed by a “continuous” suture.

continuous suture, and Fig. 42 its appearance when the margins of the incision have been approximated and the ends secured.

The disadvantage of the continuous suture is, that if one part of the line of suture “cuts out,” the approximation of the margins of the entire wound is imperilled.

When a series of sutures has been inserted for the closure of

an external wound, each one should be tied separately by making a "reef" knot. Care must be taken not to tie what is called a "granny" knot, as it is liable to slip, and hence allow the

FIG. 43.—Method of tying a "reef" knot.

margins of the cut to become slightly separated. Fig. 43 shows the method of tying a "reef" knot, and Fig. 44 a "granny"

FIG. 44.—A "granny" knot.

knot. When silk-worm gut is used for closing an external wound, the best method of tying it is by the first stage of a

FIG. 45.—True "surgical" knot, first stage.

so-called true surgical knot. Fig. 45 is an illustration of this method of tying a suture, whilst Fig. 46 shows the completed knot. This method of tying sutures will also be found to be

very useful in those cases in which it is somewhat difficult to keep the margins of the incision in exact apposition during the making of the second "hitch."

Fig. 47 is a representation of a wound closed by a series of "interrupted" sutures of silk-worm gut, each suture being secured by the double "hitch" of the surgical knot.

When a suture is tied, care should be taken not to fasten it

FIG. 46.—True "surgical" knot, completed.

too tightly, otherwise the suture may cut out, or an unnecessary amount of scarring may result. Each suture should be tied only tight enough to keep the margins of the wound in exact apposition. When the incision is a deep one, or the cut surfaces are very extensive, the above methods of closing a wound are

FIG. 47.—A wound closed by "interrupted" sutures, each being secured by the "double hitch" of the true "surgical" knot.

insufficient, since the deeper parts of the cut are not brought together by the sutures. In order to avoid non-approximation of the deeper parts of an incision, "buried" sutures are sometimes inserted. This method is of much use in closing wounds of the abdominal walls; but in the extremities, as after amputations or the removal of tumours, the cut surfaces can in nearly all cases be brought into exact apposition by the careful application of bandages.

Introduction of drainage tubes.—A drainage tube is rarely required in the treatment of a wound which has been made by a surgical operation. In all cases of clean incised wounds, where the cut surfaces can be brought into apposition by the insertion of sutures and the application of a dressing and bandages, no drainage is necessary. When, however, extensive cut surfaces have been made, and there has been much oozing of blood, or the tissues were œdematous at the time of operation, it is advisable to leave an angle of the wound unclosed, and not to apply the sutures in the rest of the incision too closely or too tightly. This precaution will allow of the necessary escape of blood and lymph from the depths of the wound, and its absorption by the overlying dressing. It occasionally happens that it is not possible to effect complete approximation of the deeper portions of a wound—as after the extirpation of a large tumour with deep connections, or after the removal of abdominal or pelvic tumours which had extensive connections or adhesions; and in these cases it is advisable either to put in a drainage tube, or to pack that portion of the cavity whose walls cannot be approximated with a long strip or tampon of aseptic gauze, one extremity of which is allowed to protrude from an angle of the external wound, which is left open for the purpose. Usually this method of packing with gauze will be found more efficacious than the use of a drainage tube. In both cases the strip of gauze or the drainage tube is removed at the end of twenty-four or at most forty-eight hours, unless some complication such as hæmorrhage or suppuration has occurred.

A drainage tube or a tampon of gauze ought to be placed in those wounds which are the seat of septic processes at the time of operation, and also in cases in which a fistula is very liable to result, as after certain operations on the alimentary canal and the urinary system.

Application of dressings.—When the suturing of an operation wound has been completed, the entire field of operation should be sponged dry, and then dry sterilised dressings of gauze (which may or may not be impregnated with chemical antiseptics) carefully applied and fixed in position by firm and even bandaging. If there is any possibility of contamination of the dressings from without—such as by soaking with urine—a layer of impervious material should be placed outside the gauze dressings and bandages.

After-treatment.—The treatment which ought to be adopted after the performance of a surgical operation can be considered

from two aspects, namely—(a) The after-treatment of the wound, and (b) the after-treatment of the patient generally.

(a) *The after-treatment of the wound.*—When the wound is of an aseptic nature, and no drainage tubes or tampons of gauze are inserted, the dressings which have been applied at the end of the operation can be left on for seven or eight days, and then removed and replaced by others. If, however, much oozing occurs, and the dressings become soaked with exudations, they ought to be removed and replaced by fresh ones earlier. The sutures which have been inserted for the closure of the external wound should be removed at the end of five or seven days, especially if they are of silk. If silk sutures are left longer than this they are very liable to assist in the development of “sutural” or “stitch” abscesses. When silk-worm gut is used it can be left longer—ten days or a fortnight—without an abscess of this nature being formed. When drainage tubes or tampons of gauze are inserted in an operation wound, they should be removed at the end of twenty-four hours, and replaced by others if it is considered to be necessary.

(b) *The general after-treatment.*—Careful attention must be paid to the feeding of the patient, and also to the hygienic conditions and surroundings. The part of the body which has been the seat of operation should be kept at rest, either by simply keeping the patient in bed, or by applying some form of splint or stiff apparatus. The air should be allowed to circulate freely in the neighbourhood of the dressings, so as to prevent the atmosphere becoming moist, foul, and contaminated with the exhalations from the skin. This can be effected by raising the bed-clothes from the affected portion by means of a cradle.

CHAPTER IV.

OPERATIONS UPON THE STOMACH AND INTESTINES.

THE majority of operations upon the stomach and intestines are carried out through an incision in the anterior abdominal wall. In lumbar colotomy, however, the incision is made in the loin; and in operations upon the rectum, the posterior half of the perinæum or the region of the sacrum is the seat of the incision.

Hence the *first stage*, in most operations upon the stomach or intestines, is the making of an incision through the abdominal parietes, and the opening of the peritoneal cavity. This incision is often made in the middle line, through the linea alba, so as to avoid the division of nerves. It is better, however, to make the incision about half an inch to one or other side of the middle line, and, after division of the skin, subcutaneous fascia, and anterior layer of the sheath of the rectus abdominis muscle, to define the inner margin of this muscle and retract it outwards, and then divide the posterior layer of the rectus sheath and the parietal peritoneum in the same line as the original incision. This method of incising the abdominal wall tends to minimise the risk of occurrence of a ventral hernia at a later period. If it is not possible or convenient to make the incision, either on one side of the middle line or in the middle line, it should be so placed that the nerves which supply the muscles of the anterior abdominal wall are exposed to as little injury as possible. These nerves run for the most part in an oblique direction from behind downwards and forwards. The large blood vessels of the anterior abdominal wall—the deep epigastric artery which runs from opposite the mid-point of Poupart's ligament to the umbilicus, and the superior epigastric artery which runs from the seventh costal cartilage to the umbilicus—should also be avoided.

The length of the parietal incision varies according to the

nature of the operation. The longer the incision the greater is the liability to a subsequent ventral hernia. It is, however, most important that the surgeon should have an unobstructed view of the organs upon which he proposes to operate, and sufficient room for the easy performance of the necessary manipulative procedures.

When the skin, fasciæ, and muscular strata of the abdominal wall have been divided, all hæmorrhage should be arrested by the application of ligatures to the bleeding points, and the wound sponged dry. Next, the peritoneal cavity is opened. The parietal peritoneum can usually be recognised by the loose fatty tissue layer—subperitoneal fat—which lies between its external aspect and the transversalis fascia, and also by the arborescent arrangement of the blood vessels upon its surface. The peritoneal cavity is most safely opened by picking up a piece of the membrane with dissecting forceps, and cutting upon the points with the scalpel. When this has been done, the aperture is enlarged by pushing through it the points of a pair of dissecting forceps, and cutting between them. The fingers of the left hand may then be introduced, and the opening further enlarged by cutting between the fingers, which serve as a director and keep the intestine and omentum out of the way. When a piece of the parietal peritoneum is picked up with the dissecting forceps, the underlying intestine or omentum slips away, if the normal peritoneal cavity has not been obliterated by peritonitis and the formation of adhesions.

The *second stage* of an abdominal operation of this kind is the finding of the anatomical structure upon which it is proposed to operate, and the performance of whatever procedure is necessary.

When the object of the operation has been effected, in some cases, such as the resection of a portion of the alimentary canal or the establishment of an intestinal anastomosis, the parietal wound is closed; whilst in others, such as the creation of an artificial anus or the drainage of a purulent collection, it is left open so as to allow of the insertion of a drainage tube or packing with strips of gauze.

Washing out, or irrigation of the peritoneal cavity.—Before the closure of the wound in the parietes, care must be taken to remove by sponging or "local" irrigation all traces of blood or any kind of extraneous matter from the peritoneal cavity. In all cases where the peritoneum has been soiled by septic material from the alimentary canal, or by pus, it is advisable to thoroughly irrigate the contaminated area with

warm sterilised salt solution (0·75 per cent.), or an antiseptic solution such as biniodide of mercury (1 in 2000), or carbolic acid (1 in 50).

Methods of intestinal suture.—For the performance of operations upon the stomach and intestines, it is necessary for the surgeon to be familiar with some of the methods of intestinal

FIG. 48.—Diagrammatic section of a portion of gut wall, showing the method of insertion of a Lembert's suture.

It should be specially noted that in this and in the following figures this suture passes *through* the submucous tissue.

|-------------------|--|--------------------|
| a. Peritoneum. | | c. Submucous coat. |
| b. Muscular coat. | | d. Mucous coat. |

suture. The principal of these will now be described. The most important of these are—

- (a) Simple continuous suture.
- (b) Simple interrupted suture.
- (c) Lembert's suture.
- (d) Czerny's suture (Czerny-Lembert).
- (e) Gussenbauer's suture.

FIG. 49.—Diagrammatic section of a portion of intestinal wall, showing method of approximation by Lembert's suture.

(f) The Czerny-Lembert-Wölfler suture.

(g) Chaput's suture.

(h) Halsted's mattress or quilted suture.

(a) and (b) *The simple continuous and simple interrupted sutures* have already been described on p. 37.

(c) *Lembert's suture.*—Fig. 48 shows the mode of inserting a suture by Lembert's method, and Fig. 49 the manner in which the serous surfaces are brought together.

Fig. 50 is an illustration of an incision for the closure of which a series of Lembert's sutures has been inserted.

Fig. 51 shows the appearance of such an incision when the sutures have been tied and the ends cut short.

In inserting a Lembert's suture, the needle is made to transfix the serous and muscular coats and penetrate the sub-mucous coat of the intestine on one side of the wound, and

FIG. 50.—Illustration of an incision, with a series of Lembert's sutures inserted but not tied.

then the same proceeding is repeated on the other side, care being taken not to pierce the mucous coat.

(d) *Czerny's suture* really consists of two superimposed tiers of Lembert's sutures; the first tier unites the serous and muscular coats of the margins of the wound, whilst the second is placed a short distance beyond. All the sutures of the first

FIG. 51.—The same incision, with the sutures tied and the ends cut short.

tier are inserted, tied, and cut short before any of the second tier are passed.

Fig. 52 shows the method of inserting this variety of suture.

(e) *The suture of Gussenbauer* is in reality a double Lembert (or Czerny) suture, inserted with one thread at the same time (Figs. 53 and 54).

(f) *The Czerny-Lembert-Wölfler suture, or suture in three stages.*—This method of suture is essentially a Czerny's suture,

with the addition of a tier of sutures which unite mucous membrane to mucous membrane, as shown in Fig. 55.

(g) *Chaput's suture*.—The essential point in this suture is

FIG. 52.—Czerny's suture : Diagrammatic representation of method of inserting Czerny's suture.

A. First suture.

B. Second suture.

FIG. 53.—Gussenbauer's suture : Section of gut wall, showing method of insertion.

FIG. 54.—Gussenbauer's suture : Section of gut wall, showing manner of approximation as suture is tied.

the preliminary separation for a short distance of the mucous membrane from the muscular and serous coats. When this has been done, the margins of the mucous membrane are united by the insertion of a series of simple interrupted sutures. Next, the serous and muscular coats are slightly everted and fixed in

apposition by a series of simple interrupted sutures, according to the method shown in Fig. 56.

(h) *Halsted's quilted or mattress suture* is inserted according to the method shown in Fig. 57, care being taken to ensure that the needle passes through the muscular coat and pierces part of the sub-mucous layer.

Of these methods of intestinal suture the best is probably a combination of a simple interrupted suture for the mucous and submucous layers, and a

FIG. 55. — Czerny - Lembert - Wüller suture : Section of intestine, showing manner of insertion, etc., of the three tiers of sutures.

FIG. 56. — Chaput's suture : Section of intestines, showing method of insertion and manner of approximation.

Lembert's or Halsted's suture for the remainder.

This method of closure of intestinal wounds produces less puckering of the tissues, and hence causes the minimum of contraction.

Method of closure of the parietal wound.

—The incision through the abdominal wall may be closed in the following ways :—

1. By one row of simple interrupted sutures, each suture passing through all the layers of the abdominal wall.

2. By two tiers of sutures—one being a simple interrupted suture for the peritoneum, and the other a row of simple interrupted sutures which pass through the rest of the abdominal wall.

3. By three tiers of sutures—the first, a simple interrupted suture through the peritoneum; the second, a series of buried

FIG. 57. — Halsted's quilted suture : Appearance of a wound with a series of these sutures inserted.

interrupted sutures, which approximates the muscular strata; and the third, interrupted or continuous, for the fasciæ and skin.

The best of these three methods, in the majority of instances, is that by three tiers of sutures.

When more than one tier of sutures is inserted, the deep ones are tied and the ends cut short before the next row is inserted.

Position of patient.—When operations upon the abdominal viscera are about to be performed, in the majority of instances the most suitable and convenient position is to have the patient lying in the dorsal decubitus, with the knees slightly drawn up

FIG. 58.—Appearance of patient when placed in “Trendelenberg” position.

or raised. When, however, it is necessary to deal with the pelvic viscera, or with intra-pelvic conditions of portions of the intestines, considerable aid in manipulation and ready exposure of the parts to be operated upon may be obtained by raising the pelvis, or placing the patient in what is generally known as the “Trendelenberg” position. Fig. 58 is an illustration of a patient placed in this position. The advantages of this position are that the intestines tend to fall upwards into the upper portion of the abdominal cavity, and so do not interfere with the operator’s free view of the pelvic cavity and its contents, whilst the pelvic viscera or any pathological tumour or formation within the

pelvis fall forwards and upwards, and can more readily be brought into a wound in the abdominal parietes. When the pelvis is the seat of a localised peritonitis, or a collection of purulent matter in connection with one of its viscera, very great care must be taken, when this position is made use of, to thoroughly shut off the upper portion of the abdominal cavity with sponges or pads, and so prevent the escape of purulent matter upwards, and consequent direct contamination and infection of the peritoneum in this part.

In the majority of instances, when cases of intra-pelvic suppuration are being dealt with, I think it is inadvisable to place the patient in the "Trendelenberg" position.

The following operations upon the stomach and intestines will now be described :—

OPERATIONS UPON THE STOMACH.

Gastrostomy.
Gastrotomy,
Gastrectomy.
Pyloroplasty.
Pylorectomy.
Gastro-enterostomy.
Operation for perforated gastric ulcer.

OPERATIONS UPON THE SMALL INTESTINE.

Closure of perforating wound of the intestine.
Resection of the intestine—
1. Suture methods (circular enterorrhaphy, Maunsell's method).
2. With the aid of a mechanical appliance (Murphy's button, a bone tube, or a bone bobbin).
Formation of artificial anas.
Operations for perforation of duodenal and typhoid ulcers.

OPERATIONS UPON THE LARGE INTESTINE.

Removal of vermiform appendix.
Operation for suppurative appendicitis.
Excision of cæcum.
Intussusception.
Resection of large intestine.
Colotomy—
1. Inguinal.
2. Lumbar.

OPERATIONS UPON THE RECTUM.

For hæmorrhoids.
For fistula in ano.
Excision of part of rectum—
1. Perineal method.
2. Sacral method.
Operation for imperforate rectum and anus.

OPERATIONS UPON THE STOMACH.

Gastrostomy.—The operation of gastrostomy has for its object the establishment of a permanent fistulous communication between the cavity of the stomach and the surface of the body.

The stomach is situated in the upper part and on the left side of the abdomen, but its exact extent and relations depend upon

FIG. 59.—Stomach and its relations as seen from the front when the liver has been removed.—After TESTUT.

the amount of its distension. In every condition, however, the main part of the viscus occupies the left hypochondrium and the left half of the epigastrium.

Indications.—The indications for the performance of gastrostomy, may be said to be—(a) Fibrous stricture of the œsophagus, which cannot be dilated; and (b) carcinoma of the œsophagus, which is beginning to cause obstruction to the passage of food.

Before deciding to recommend the operation in the latter class of case, very careful consideration must be given to the general condition of the patient, to the extent of emaciation which has occurred, and to the possibility of the occurrence of secondary growths or of extension of the malignant process to one of the surrounding or adjacent anatomical structures, such as the larynx, trachea, or bronchus. When the disease is in an advanced stage, and the patient has begun to show signs of cancerous cachexia, or when there are signs of extension to any part of the respiratory system, an operation ought not to be recommended. When an operation is performed at this stage, no material advantage is gained; and in the majority of instances the patient dies as the direct result of the operative procedure, the tissues not having sufficient vitality to repair the injuries made by the scalpel. The operation, if it is to be performed at all, must be done in the early stages of the disease. Then a patient's life can undoubtedly be prolonged, and his condition made much more comfortable. It should be borne in mind, however, when discussing the advisability of performing this operation, that when the patient has recovered from the operation, he usually requires careful attention and assistance in feeding. Hence medical or nursing assistance is usually requisite until the end of his days. Therefore, as regards this operation, poor or hospital patients are at a disadvantage when compared with the wealthy. Intelligent patients may be taught how to feed and look after themselves, but often in the case of a poor patient the condition after the operation, when he has returned to his home, is as bad or worse than before anything was done.

Special instruments.—Rubber tube or gum elastic catheter, sewing needles.

Position.—The patient is placed in the dorsal position, near the left side of the table. The operator stands on the left side, and the chief assistant on the other side directly opposite to him.

Varieties of operation.—Many varieties of gastrostomy have been described and practised. Those which I consider most useful are—(a) Creation of a simple gastric fistula; (b) Frank's or Albert's operation; and (c) Witzel's operation. It is not always possible to perform Frank's or Witzel's operation, owing to the difficulty of bringing sufficient stomach into the wound. When, however, a sufficient amount of stomach can be brought into the wound, I think Frank's operation is to be preferred; when this cannot be done, if possible, Witzel's operation should be carried out; and in those cases in whom the stomach is

bound down by adhesions, especially when the growth in the œsophagus is situated at the cardiac end, a simple gastric fistula should be the aim of a surgical procedure.

The three forms of operation will now be described in detail.

Creation of a simple gastric fistula.—This form of gastrotomy is similar to that which has been proposed and practised by many of the older surgeons. The operation, as generally performed, is divided into two distinct stages, from three to five days being allowed to elapse between each. The first stage comprises incision of the abdominal wall, finding a suitable portion of the stomach, and fixation of it to the margins of the parietal wound. The portions of the parietal incision which are not required for fixation of the selected part of the stomach are closed by the insertion of salmon-gut sutures. The second stage, performed after the expiration of from three to five days, consists in making a small incision through the centre of the selected area of the stomach wall, and the introduction and fixation of a small catheter or rubber tube.

Operation.—**FIRST STAGE.**—(a) *Parietal incision, finding of stomach and bringing it into parietal wound.*—An incision, $2\frac{1}{2}$ to 3 in. long, according to the obesity of the patient, is made, which commences immediately below the left costal margin at the junction of the eighth and ninth costal cartilages, and extends vertically downwards. The skin, subcutaneous fasciæ, and anterior layer of the sheath of the rectus abdominis muscle are first incised, and the vertical fibres of the rectus muscle exposed. These are readily recognised by their fleshy appearance and their vertical direction. When this has been done, a probe-pointed steel director is taken, and the fibres of the muscle separated for the entire length of the incision. The separation of these fibres should be at least half an inch from the left lateral margin of the muscle; and if the incision happens to have been made too far to the left, the inner margin of the wound should be retracted inwards, so as to allow of the separation of muscular fibres half an inch from the outer margin of the muscle. When this separation has been satisfactorily effected, the posterior layer of the sheath of the rectus muscle and the extra-peritoneal fat and peritoneum are divided in the line of the original incision. The peritoneal cavity is thus opened. The stomach is sought for by passing the fingers upwards and towards the left. It is readily recognised by the smoothness and thickness of its wall, its reddish-pink colour, and by having omentum attached to both its upper and lower borders (the gastro-hepatic omentum is attached to the lesser curvature and

the great omentum to the greater curvature). When any difficulty is experienced in finding the stomach, the forefinger and thumb of the left hand should be passed upwards in the wound until the lower surface of the left lobe of the liver can be felt. Then this surface is traced backwards to the attachment of the gastro-hepatic omentum, when, by following the anterior surface of this omentum downwards, the anterior aspect of the stomach will always be found. When the stomach has been recognised, it is brought into the parietal wound, and an area selected for fixation to the abdominal wall. This area should be in the cardiac portion of the viscus and some distance above the lower or greater curvature.

(b) *Fixation of selected area of stomach.*—The selected portion of stomach, comprising a circle $\frac{3}{4}$ in. in diameter, is fixed to the margins of the upper portion of the parietal wound by the insertion of a series of fine silk sutures. As a general rule, eight to ten sutures are introduced on each side, and one above and one below. The lateral sutures are inserted thus: With dissecting forceps a portion of the stomach wall at the margin of the selected area is picked up, and then a half-curved needle armed

FIG. 60.—Gastrostomy, external incision.

with a suture is passed through the serous, muscular, and part of the submucous coats of the stomach, care being taken to avoid puncturing the mucous coat. If not more than a quarter or a third of an inch of the stomach wall is seized with the forceps, the mucous coat slips away, and hence is out of danger. Next the needle is passed through the abdominal wall, all the layers being included except the vertical fibres of the rectus abdominis muscle, about a quarter of an inch from the incised margins. Sutures are introduced in this manner for the entire length of each margin of the selected area. Next, the end sutures are inserted. An armed needle is passed through one margin of the parietal incision, commencing on the skin aspect; next through the serous muscular and submucous coats of the stomach

at one extremity of the selected area; and, finally, through the abdominal wall in the corresponding part of the parietal incision, so that the needle emerges from the skin surface. A similar end suture is passed at the other extremity of the selected area; and then, finally, salmon-gut sutures are inserted so as to close the remaining portions of the parietal incision. Now the sutures are tied—first, the lateral silk sutures; secondly, the end silk sutures; and then the salmon-gut sutures.

A small guiding suture is now passed through the serous and muscular coats of the stomach in the centre of the selected area, and dressings applied. The first stage of the operation is thus completed. The patient is kept at rest and fed on very light and easily digestible foods for from three to five days, and then the second or final stage of the operation is carried out.

SECOND STAGE.—*Opening of stomach.*—The dressings are removed, lymph and serous discharge sponged from the surface of the selected area of the stomach, and the guiding suture picked up. A sharp tenotome or very narrow-bladed scalpel is taken, and pushed through the stomach wall at the point of attachment of the “guiding suture.” A piece of this rubber tubing, or gum elastic catheter, is then passed along the tenotome into the lumen of the stomach, and the instrument withdrawn. This tube is fixed in position by a suture, and through it small quantities of liquid food are introduced. The surfaces of the wound are carefully packed with antiseptic dressings, and the opening in the rubber tube or catheter temporarily closed. The administration of an anæsthetic is not necessary for this stage.

The advantages of this operation are—(a) The small amount of risk of establishment of peritonitis; (b) the applicability of the operation to nearly all patients suffering from carcinomatous affections of the œsophagus; and (c) the small amount of shock which is produced by the actual operation. The disadvantages of the operation are—(a) The tendency to leakage of stomach contents or gastric juice, and the consequent causation of an eczematous condition of the skin at the margin of the fistulous opening; and (b) the possibility of opening the peritoneal cavity at the second stage of the operation, and subsequent feeding of the patient into the peritoneum. This latter complication I have seen occur on more than one occasion.

Frank's operation.—The operation itself may be divided into three stages, namely—

(a) *Incision of the abdominal wall.*—An incision from 2 in. to $2\frac{1}{2}$ in. in length is made in the abdominal wall, parallel to and 1 in. below the costal margin, and opposite the cartilages of

the seventh, eighth, and ninth ribs of the left side (Fig. 61). The scalpel is made to divide the skin, fasciæ, and anterior layer of the sheath of the rectus abdominis muscle; and when the surface of the muscle is exposed, its fibres are separated in a vertical direction for about 1 in., the separation being about one finger's-breadth from the linea semilunaris. By this means the posterior wall of the sheath is exposed. This is now divided in the line of the original incision, the margins of the wound in the rectus being retracted, together with the underlying transversalis fascia, subperitoneal fat, and peritoneum.

FIG. 61.—Gastrostomy (Frank's or Albert's method): Position of incisions.

a. First or abdominal incision.
b. Second or thoracic incision.

(b) *Exposure of the stomach and fixation of a portion of the viscus in the abdominal wound.*—The stomach is sought for by passing the fingers of the right hand into the peritoneal cavity. It can be recognised by the thickness of its walls,

the attachment of its superior margin to the liver by means of the gastrohepatic omentum, the smoothness of its surface, and

the absence of sacculations and appendices epiploicæ. When the stomach has been recognised, a portion of it is brought into the wound, and a point selected upon its anterior aspect opposite to the parietal incision and about $1\frac{1}{2}$ or 2 in. above the greater curvature. A thick suture is passed through the serous and muscular coats of the organ at the point selected, and this is left long and used to lift up the stomach during the later stages of the operation. A cone of the anterior wall of the stomach (Fig. 62) is lifted up into the abdominal wound, and its base sutured to the margins of the incision by the insertion of a ring of fine silk

FIG. 62.—Gastrostomy (Frank's or Albert's method): Cone of stomach brought out of first incision and sutured to serous and muscular strata of abdominal wall.

sutures. Each suture passes through the serous, muscular, and submucous portions of the wall of the stomach, and also the serous and muscular strata of the anterior abdominal wall.

These sutures are inserted at intervals of about one-third of an inch, and all are introduced before any are tied. The cone of the stomach which is brought out in this manner in most cases is about $1\frac{1}{2}$ in. in length, but this depends upon the thickness of the anterior abdominal wall. If the abdominal incision is larger than the portion of stomach, the ends of the incision are closed by the insertion of sutures in the usual manner.

(c) *Incision of the thoracic wall immediately above the costal margin, suture of the stomach to the margins of this opening, and formation of a gastric fistula.*—An incision three-quarters of an inch in length is now made over the costal margin, opposite the middle of the first incision and parallel to it. This is deepened until the deep fascia has been divided and the surface

FIG. 63. — Gastrostomy (Frank's or Albert's method): Operation completed. The opening in the stomach is attached to the upper incision.

of the external oblique exposed (Fig. 61, b). The bridge of skin and fascia which separates the two incisions is lifted after the deep fascia has been detached from the muscle. The long loop of silk which is fixed to the stomach is passed underneath this bridge of skin, and brought out through the second incision, and traction exerted upon it. The cone of the stomach is thus drawn underneath the cutaneous bridge.

A small aperture, about half an inch in length, is then made in the wall of the protruded part, and the margins of this incision are fixed to those of the wound in the skin by the insertion of sutures. Each suture passes through the skin and fascia, and then through the entire thickness of the wall of the stomach (Fig. 63). The margins of the first incision are then united by a continuous suture.

The advantages of this operation are: The stomach can be opened at the time of operation, the margins of the aperture and the walls of the fistula can be held in apposition during the intervals between feeding, regurgitation of food is prevented, and peritonitis is not likely to be induced.

Witzel's operation.—The peritoneal cavity is opened as in the preceding operation. When this has been done, a portion of the anterior wall of the stomach is brought into the wound, and a point selected about $1\frac{1}{2}$ in. above the greater curvature. With a tenotomy knife or scalpel an aperture is made in the stomach wall, sufficiently large to

admit a rubber tube, as shown in Fig. 64. The dark circle indicates the position of the incision.

Next, a series of Lembert's sutures are inserted in the stomach in such a manner that they pass over the tube, and when they are tied they convert a portion of the anterior wall of the stomach into a canal, commencing at the aperture which has already been made. Fig. 65 shows these sutures inserted and not tied, and the tube in position; and Fig. 66, the sutures tied, and the ends cut short.

The margins of the upper portion of the canal are united to those of the abdominal wound, and the remaining portions of the parietal incision closed. Figs. 67 and 68 illustrate these stages of the operation.

FIG. 64.—Gastrostomy (Witel's operation): Method of opening stomach and fixing tube in a groove formed from anterior surface of viscus.

The advantages of this operation over the preceding one are, it does not cause so much constitutional disturbance, and it is easier to bring the requisite amount of stomach wall into the wound. The disadvantage is, that it is not quite so easy a matter to prevent regurgitation.

When there is difficulty in bringing the stomach into the external wound, or it is thought that the patient will not stand the more severe "Frank's" operation, this modification of gastrostomy may often with advantage be performed.

Gastrotomy.—The term gastrotomy implies the making of an opening through the wall of the stomach. This opening is

usually closed immediately after the object of the operation has been attained.

Indications for operation.—Gastrotomy has been performed

FIG. 65.—Gastrotomy (Witzel's operation): Rubber tube passed through aperture in stomach, and row of Lembert's sutures inserted.

for the following conditions:—(a) The presence within the stomach of a foreign body which will not readily pass through

FIG. 66.—Gastrotomy (Witzel's operation): Method of formation of oblique groove or channel from anterior wall of stomach. The row of Lembert's sutures are tied.

the pylorus; (b) fibrous constriction of the pylorus, or of the lower portion of the œsophagus; (c) localised malignant growths of the stomach, which are limited to the mucous membrane;

(d) impaction of a foreign body in the lower part of the cesophagus.

Special instruments.—As for gastrotomy.

Position.—The patient is placed in the dorsal position, the

FIG. 67.—Gastrotomy (Witzel's operation): Method of fixation of margins of aperture of artificial channel in wall of stomach to margins of external wound.

operator stands on the left side, and the chief assistant opposite to him.

Before commencing the operation, it is advised that the stomach should be washed out with a dilute alkaline solution, so as to render it as aseptic as possible, and diminish the risk of the occurrence of peritonitis.

Operation.—The operation of gastrotomy may be divided into four stages, namely—

(a) *Abdominal incision.*—An incision 3 in. in length is made either in the middle line,—about $1\frac{1}{2}$ in. to left of it,—over the left rectus abdominis muscle and parallel with the direction of its fibres; the sheath is thus opened and the muscle drawn outwards, so that the posterior portion of the sheath may then be divided and the abdominal cavity opened in the line of the skin incision. If the operation is performed for the removal of a foreign body, and the situation of this structure can be felt, the incision is

FIG. 68.—Gastrotomy (Witzel's operation): Appearance of abdomen when operation is completed.

usually made over it; and if it is being done for the relief of a fibrous constriction of the pylorus, the incision is made half an inch to the right of the linea alba.

(b) *Finding of stomach, bringing it into the parietal wound, and location of the foreign body or other pathological condition.*—The fingers are introduced into the wound, and the stomach felt for, and also the locality of the foreign body, fibrous constriction, or growth. Care must be taken when palpating the stomach not to cause injury to the walls, if a sharp foreign body is present. The stomach is then brought into the parietal wound, and the surrounding portion of the peritoneal cavity packed with aseptic Turkey sponges or flat cellular pads.

(c) *Incision of the stomach wall and removal of the foreign body, or treatment of the special pathological condition for which*

FIG. 69.—Gastrotomy: Abdominal incision.

the operation is undertaken.—An incision is made through the stomach wall in a direction at right angles to the long axis of the viscus, so as to avoid injury to the chief blood vessels. The length of this incision varies according to the size of the foreign body which it is wished to remove, or to the nature of the constriction, or the size and locality of the malignant growth. The foreign body is removed through the aperture made, care being taken not to lacerate or damage the walls of the stomach. If the operation

is performed for the relief of a fibrous stricture, either of the pylorus or the lower portion of the œsophagus, the forefinger of the right hand is passed into the cavity of the stomach towards the seat of the constriction, and the narrowed portion of the canal dilated by gently forcing the finger through the stenosed part.

(d) *Closure of wound.*—The area of the wound in the stomach wall is carefully sponged with aseptic sponges, and the aperture closed. The mucous membrane is joined to mucous membrane by the insertion of a continuous suture of catgut, the muscular coats are united with interrupted sutures of fine silk, and the serous and superficial muscular coats by the insertion of a series of Lembert's sutures. When the incision in the stomach has been closed thus, all sponges are removed from the peritoneal cavity, and the exposed peritoneum carefully cleansed. The parietal wound is then closed in the usual manner.

In the after-treatment of a case of this kind, no food is given by the mouth for the first three or four days, the patient being fed with nutrient enemata.

The operation of gastrotomy, when it is performed for the dilatation of a fibrous stricture of the pylorus, has been called "Loreta's operation."

Gastrectomy.—This operation comprises removal of a part or the whole of the stomach. The so-called "complete" gastrectomy, or excision of the entire viscus, which has been performed and described a very limited number of times, has consisted in removal of the greater portion of this organ—a small part of the cardiac end being left, in order to make a satisfactory anastomosis with the duodenum.

(a) *Indications.*—Localised destruction of the stomach walls, due to injuries from without or ulceration from within, where the damage has been so great that removal of the injured parts is deemed advisable before proceeding to repairing the lesion by plastic operation.

(b) *Carcinoma*, affecting a limited portion of the stomach wall and not associated with secondary growths.

Special instruments.—Large intestinal clamps and rubber tubing.

Position.—The patient is placed in the dorsal position. The operator stands on the left side and the chief assistant opposite to him.

Operation.—The operation of gastrectomy may be divided into four stages—

(a) *Abdominal incision.*—An incision 3 to 4 in. long, similar to that in gastrotomy (Fig. 69), is made about $1\frac{1}{2}$ in. to the left of the middle line, commencing 1 in. below the costal margin and extending vertically downwards. The various strata of the abdominal wall are successively divided, the rectus abdominis muscle being cut through parallel with its fibres, and the peritoneal cavity opened. Should the incision prove insufficient, a second incision may be made at right angles to it, so that a T-shaped opening results. In this manner less dragging upon the stomach is necessary, and less constitutional disturbance results to the patient.

(b) *Finding of the stomach, location of the lesion, and determination of the part to be removed.*—The margins of the parietal incision are retracted with wide abdominal retractors, and a careful inspection made of the stomach and its surroundings, so as to discover the limits and extent of the lesion or malignant growth, and so determine the lines where

resection of the stomach and duodenum are to be effected. These lines of resection ought to be at least 1 in. on each side of the margins of a malignant tumour. At this stage of the procedure a careful investigation of the liver, the lymphatic glands in the gastro-hepatic omentum and in front of the spinal column, should be carefully carried out, so as to ensure the absence of any secondary cancerous deposits in these regions, since, if any are found in the liver or lymphatic glands in front of the spinal column, the operation ought to be abandoned. When, however, the lymphatic glands in the gastro-hepatic omentum are alone and not extensively involved, the operation may be completed, and all implicated lymphatic glands and vessels excised.

The stomach is next brought forward into the wound, with the diseased area presenting, and the surrounding portions of the peritoneal cavity packed with flat marine sponges or cellular pads. The large intestinal clamps are now taken and placed, one on the proximal side of the part which is to be removed and the other on the distal, each clamp being applied about $2\frac{1}{2}$ in. from the margins of the diseased portion, or an inch or more from the lines where it has been determined to perform resection. When applying the proximal clamp, a small aperture should be made in the gastro-splenic omentum so as to allow one blade of the clamp to be passed behind the stomach. The distal clamp is applied to the duodenum, or to the pyloric portion of the stomach, according to the necessities of the individual case. These clamps control hæmorrhage, prevent escape of intestinal contents during the operation, enable the assistant to hold the stomach well in the wound, and so materially help the operator.

(c) *Separation and removal of required portion.*—The stomach being lifted forwards by the assistant in charge of the clamps, separation of the required portion is commenced by the surgeon cutting through with scissors the gastro-hepatic omentum immediately above its attachment to the lesser curvature of the stomach, and the gastro-splenic omentum and part of the great omentum just below their attachments to the greater curvature. The main branches of the gastric and right and left gastro-epiploic arteries which lie along the curvatures of the stomach should be seized with pressure forceps before being divided, and any other bleeding vessels picked up and ligatured. The portion of the lesser sac of the peritoneum which has been opened up should be packed with a flat sponge or pad, so as to prevent unnecessary contamination with any contents of the

stomach which may escape. The incisions through the stomach, or stomach and duodenum, are now made, care being taken to carry them as far as possible at right angles to the long axis of the viscus. Commencing above, the stomach is divided transversely by cutting with strong, blunt-pointed scissors; and as the section is made, the cut margins on the part to be removed are seized with strong pressure forceps, which serve to lift up the mass. Any bleeding points on the cut margin on the proximal side are picked up with pressure forceps and ligatured. Next, the section of the stomach or duodenum on the distal side is made in a similar manner, and thus the mass to be removed is rendered entirely separate and taken away. The cut margin of the distal portion of the duodenum is next examined, and any bleeding arrested by the application of ligatures. At this stage the intestinal clamps should be relaxed, so as to render apparent any divided blood vessels, which have so far evaded observation and not been ligatured. The area of operation is now thoroughly sponged or irrigated, so as to remove any blood clot or escaped stomach contents.

(d) *Anastomosis of cut ends of stomach and duodenum.*—The cut ends of the proximal portion of the stomach and the duodenum are brought into apposition, and if they correspond in size they are at once united; but if the opening in the stomach is too large, a portion of it is closed by suturing together the cut margins of the mucous membrane, inverting the edges, and joining the serous and muscular layers by the insertion of a series of silk sutures, introduced after Lembert's method.

When the opening in the stomach has been reduced to a suitable calibre, the edges of the openings in the stomach and duodenum are brought together and fixed by careful suturing. The cut edges of the mucous membrane are joined by interrupted sutures of silk, the posterior part being sutured first. When this has been satisfactorily completed, the serous and muscular coats of the stomach and duodenum are fixed together by a series of Lembert's silk sutures, introduced at intervals of one-sixth or one-eighth of an inch. The anastomosis being completed, the area of operation is again sponged or irrigated with an antiseptic solution, and the sponges or pads which have been used for protecting the peritoneum and adjacent abdominal viscera removed, and the intestinal clamps taken off.

A roll of gauze is passed down to the area of operation, and one end brought out through an angle of the parietal wound.

(e) *Closure of parietal wound.*—The main portion of the incision is closed by the insertion of three tiers of sutures, whilst the upper portion is left open for the exit of the roll of gauze which has been introduced for drainage purposes.

Pyloroplasty.—This operation has been recommended by Heineke and Mikulicz as superior to digital dilatation, in cases of fibrous stricture of the pylorus or the upper part of the duodenum, and appears to be productive of better and more lasting results.

Operation.—The abdomen is opened by an incision in the linea alba, as in the preceding operation, and the pylorus and the constricted portion of the duodenum brought into the

FIG. 70.—Pyloroplasty: Stomach and duodenum with line of incision in gut wall.

parietal wound. The exposed portion of alimentary canal being protected by aseptic flat sponges, an incision is made on the anterior aspect of the constricted gut in its long axis, according to the method shown in Fig. 70. The margins of this incision are then approximated as in Fig. 71, and fixed by the insertion of sutures. Three tiers of sutures are inserted, the first uniting the mucous membrane, the second the muscular coat, and the third the peritoneum. When the operation is completed, the margins of the incision are at right angles to the long axis of the affected part of the intestine.

The pylorus and duodenum are returned into the peritoneal cavity, and the external wound closed in the usual manner.

Pylorectomy, or removal of the pyloric portion of the

stomach.—In this operation the pyloric extremity of the stomach, together with the adjacent parts of the duodenum and stomach, are removed through an abdominal incision, and then the opening in the stomach is partially closed, and that part which is left open is united to the open extremity of the duodenum.

Indications.—Removal of the pylorus is rarely justifiable, but in those cases of malignant disease of the pylorus in which the pathological process is strictly localised to this part of the alimentary canal, and there are no secondary deposits elsewhere, it may be advisable to attempt the removal of the growth, with the hope of effecting a cure, or at least prolonging life for a

FIG. 71.—Pyloroplasty: Appearance of incision when sutures have been inserted and tied.

period. The operation should only be attempted in patients who are very good subjects for surgical interference.

Preliminary preparations.—For several days before the operation the stomach should be washed out with a dilute antiseptic solution, and during this period easily digestible food, which has previously been sterilised, should be given. The day previous, an aperient medicine should be administered, so as to empty the intestines as far as possible. Immediately before the patient comes into the operation room the stomach should be again washed out.

Special instruments.—Large intestinal clamps, in addition to those for gastrostomy.

Position.—The patient is placed in the dorsal position, and

near the right edge of the table. The operator stands on the right side, and the assistant directly opposite to him.

Operation.—The operation of pylorectomy may be divided into the following stages:—

(a) *Parietal incision.*—An incision 4 in. in length is made in the linea alba or in the right linea semilunaris, usually the former, and situated over the most prominent part of the tumour. The various strata of the abdominal wall are divided in the usual manner until the peritoneal cavity has been opened.

(b) *Localisation, separation, and delivery of tumour and adjacent portion of alimentary canal.*—The fingers of the right hand are introduced into the peritoneal cavity, and the position

FIG. 72.—Pylorectomy: Lines of incision in stomach and duodenum. The dark portion represents the extent of the growth.

of the affected pylorus defined. The adjacent coils of intestine and the great omentum are pushed out of the way, and protected from injury by packing the region of the tumour with flat sponges. The pylorus is next brought out through the external wound. If its attachments to the great and lesser omenta do not allow this to be done, these structures are divided for a sufficient distance along the greater and lesser curvatures of the stomach, and the cut edges tied with ligatures so as to arrest hæmorrhage. When the tumour has been brought well forward into the external wound, its relations are determined. If it is found to be localised, and there are no signs of secondary growths in the lymphatic glands of the gastro-hepatic omentum, in the liver, or in the region of the head of the pancreas (or elsewhere), it may be decided to effect its removal.

(c) *Removal of pylorus and affected portions of stomach and duodenum.*—Before commencing to remove the tumour, the contents of the adjacent portions of the stomach and duodenum are pushed onwards (if any are present), and then an intestinal clamp is applied to the stomach about three-quarters of an inch above the limits of the growth, and a second clamp to the duodenum an equal distance below it. These clamps prevent the escape of intestinal contents into the field of operation, and help the surgeon to control hæmorrhage without much difficulty. When the clamps have been applied, both the stomach and duodenum are divided with strong scissors or a scalpel, and the tumour freed from any other connections which it may have. Care must be taken in making these sections, that the common

FIG. 73.—Pylorotomy: Affected portions of gut removed, and part of incision in stomach closed by sutures.

bile duct, the portal vein, and the hepatic artery are avoided. They lie behind the first portion of the duodenum, and then between the two layers of the gastro-hepatic omentum. The tumour having been removed, the cavities of the exposed parts of the stomach and duodenum are carefully sponged so as to render them as aseptic as possible, and then the clamps are slightly loosened by the assistant, in order to allow hæmorrhage to take place from the divided vessels, and so facilitate the application of ligatures to them.

(d) *Partial closure of wound in stomach, and union of other part to cut end of duodenum.*—A part of the divided end of the stomach is united, according to the method shown in Fig. 73. The best method of doing this is by the insertion of a continuous silk suture to the margins of the wound, a firm hold of

the mucous membrane being taken; and when this has been done, a series of Lembert's sutures are inserted, as in Fig. 73. The next stage is the union of the remainder of the wound in the stomach to the open extremity of the duodenum, and hence the re-establishment of the continuity of the alimentary canal. This can be done either by means of (1) sutures alone, by (2) sutures aided by a mechanical appliance, such as Murphy's "button," a bone tube, or a bone bobbin, or by (3) the establishment of a lateral anastomosis.

(1) *Sutures only*.—The mucous membrane and the muscular coat of the stomach are united to the corresponding portions of the duodenum by a series of interrupted fine silk sutures. The

FIG. 74.—Pylorectomy: Stomach and duodenum united by sutures.

insertion of these is commenced posteriorly, and continued forwards until the entire circumference of the bowel has been sewn up. As these sutures are inserted, each one is tied and cut short, the knot being towards the lumen of the gut. Next, the line of suture is well sponged so as to remove all traces of blood or stomach contents, and then the line of approximation is further united by the insertion of a circle of Lembert's sutures, which transfix the serous, muscular, and submucous coats only. When these have been tied and the ends cut short, the union is completed. If there is any doubt as regards the security of the sutures, it has been recommended that a graft of omentum should be fastened to the suspected portion.

(2) *Sutures aided by a mechanical appliance*.—When the portion of stomach which is not required for suture to the duodenum has

been closed, the remaining portion may be united to the open end of the duodenum by the insertion of a Murphy's "anastomosis button," or a bone tube or bobbin, into the lumen of the alimentary canal at the point of junction, and then the operation is completed by the insertion of a circle of Lembert's sutures. The advantages of this method over that of simple suture are—the greater ease with which the suturing is accomplished, the shorter time which is necessary for the operation, and the less liability there is of incomplete apposition of the divided surfaces, and hence the leakage of the contents of the stomach afterwards. The disadvantage is the liability of the button or bobbin to give rise to obstruction at a later period, owing to

FIG. 75.—Pyloroplasty: Cut ends of stomach and duodenum closed, and lateral gastro-intestinal anastomosis established.

impaction. Probably a decalcified bone tube or bobbin is safer than a Murphy's button.

(3) *Complete closure of cut ends, and establishment of lateral gastro-intestinal anastomosis.*—This operation may also be finished by completely closing the openings in both the stomach and duodenum, and then bringing a loop of jejunum into apposition with the anterior wall of the stomach, and performing a lateral anastomosis as in the operation for gastro-enterostomy (see p. 72). The advantages of this method are that those parts recently adjacent to disease are not subject to the irritation of the passage of food, and thereby the chances of recurrence in the case of carcinoma minimised; and also that, although an apparently severer operation, most patients improve more quickly, and the period of convalescence is shortened.

(e) *Return of stomach and duodenum into abdomen, and closure of external wound.*—After the approximation of the divided portions of the alimentary canal has been completed, all the sutures are cut short, the region of operation and the adjacent part of the peritoneal cavity are well sponged with an aseptic solution so as to remove all blood and other material which has escaped, and then the stomach and duodenum are returned within the abdomen. The external wound is finally closed by sutures in the usual manner. No drainage is necessary.

After-treatment.—No food should be given by the mouth for the first twenty-four or thirty-six hours, the strength of the patient being maintained during this period by the administration of nutrient enemata. Afterwards, feeding by the mouth is commenced, small quantities being given at first. Only fluid foods should be given, and these should be rendered sterile, if possible, before administration.

Gastro-enterostomy.—The establishment of an artificial communication between the cavity of the stomach and that of the intestine is called “gastro-enterostomy”; if the duodenum is the part of the intestine to which the stomach is attached, the operation is known as “gastro-duodenostomy”; if the jejunum, “gastro-jejunostomy”; if the ileum, “gastro-ileostomy”; and if the colon, “gastro-colostomy.”

Indications.—The operation of gastro-enterostomy is indicated in the following clinical conditions, namely—

(a) In those cases of malignant disease of the pylorus in which it is not advisable to attempt local removal of the growth, and in which it is probable that life will be prolonged by the establishment of an artificial communication between the stomach and the intestine.

(b) In certain cases of severe fibrous stricture of the pylorus or duodenum, which cannot be satisfactorily treated by “pyloroplasty.”

(c) Certain cases of chronic ulcer of the stomach.

Position.—The patient is placed in the dorsal position, the surgeon stands on the right side of the patient and the assistant on the left.

Special instruments.—Intestinal clamps, rubber tubing, Murphy's anastomosis button, or bone tubes.

Operation.—The operation of gastro-enterostomy may be conveniently divided into the following stages:—

(a) *Parietal incision.*—An incision from 3 to 4 in. in length is made half an inch to the left of the linea alba, commencing a short distance below the ensiform cartilage, and extending to the

umbilicus. This incision is extended until the peritoneal cavity has been opened.

(b) *Finding of stomach and required portion of intestine, and bringing them out into the external wound.*—The portion of the intestine which is usually selected is the jejunum a short distance beyond the termination of the duodenum. The great omentum is turned upwards and towards the right; then a coil of small intestine, which lies upon the vertebral column and at the level of the apex of the left kidney, is taken and traced upwards; if it is the jejunum, it will be found to have a short mesentery at its upper part, and to turn upon itself and become continuous with the duodenum. If this is verified, the coil is traced downwards, until a loop can be readily brought into the external wound and applied to the stomach. This loop is emptied of its contents by passing it between the fingers, and

FIG. 76.—Intestinal clamp.

then two intestinal clamps are applied at a distance of about 3 in. from one another. The stomach is next brought into the external wound, and an area selected on the anterior surface, about 1 in. above the greater curvature and nearer to the pyloric than the cardiac extremity. These portions of stomach and intestine are surrounded with warm sterilised towels and sponges. The formation of the anastomosis may now be performed.

(c) *Formation of anastomosis between stomach and intestine.*—The stomach and intestine may be united in a variety of ways. These methods, however, may be divided into two classes—union by *suture*, and union by *sutures* aided by a *mechanical appliance*, such as Senn's plate, a Murphy's button, or a bone "tube," plate, or "bobbin." If the "suture" method is well performed, it probably is the best. Of the mechanical appliances for this operation an anastomosis "button" or a "bone plate" are the most suitable.

Union by sutures.—The loop of intestine is applied to the stomach in such a manner that, when the communication has been established, the contents of the stomach will flow into the intestine in a direction corresponding to that of the normal peristaltic movements. This is said to be effected by twisting the intestine “half a turn” on its long axis. When this has been done, incisions $1\frac{1}{2}$ in. in length are made through the serous and muscular coats of both stomach and intestine. These incisions are so placed that they correspond with one another, and the one in the intestine is in its long axis. A series of Lembert’s sutures of fine silk is now introduced at the

FIG. 77.—Gastro-enterostomy (anterior operation): Stomach and a coil of jejunum approximated, and the margins of the incision closed on one side.

S. Stomach; J. Jejunum. *a.* The sutures of the second row tied and their ends cut short; *b.* The sutures of the third row inserted but not tied.

lower margins of the incisions, and each suture tied. Next, the mucous membrane of each viscus is divided at the bottom of the incision, and the cut margins united all round by numerous fine interrupted silk sutures. When this has been done, the serous and muscular coats on the upper margins of the incisions are united with Lembert’s sutures in a manner similar to that adopted for the lower margins. The communication between the stomach and intestine is now established, two circles of sutures preventing escape of intestinal contents into the peritoneal cavity. The area of operation is well sponged, and any weak points in the suturing sought for, and, if found, closed by the insertion of additional sutures. Next, all sponges are removed, together with

the intestinal clamps, and then the stomach and loop of intestine are returned into the peritoneal cavity.

Union by sutures aided by "mechanical appliances."—The methods of using a Murphy's anastomosis "button," or a bone "tube" or "bobbin," are described in connection with the operation of removal of portions of the small intestine.

(d) *Closure of external wound.*—When the anastomosis has been completed, and the contaminated part of the peritoneum well sponged, the margins of the parietal incision are united in the ordinary manner by the insertion of one or more tiers of sutures. The above, in my opinion, is the most superior method of gastro-enterostomy, and yields the best results. Von Hacker and many other surgeons, however, claim that better results are obtained by uniting the jejunum with the posterior aspect of the stomach, after dividing a portion of the transverse mesocolon. The method of performing this operation is shown in Fig. 78.

Treatment of perforated gastric ulcers.—Ulcers of the stomach which lead to perforation of the walls may be either of the "acute perforating" or the "chronic" variety. The perforation usually occurs

suddenly without any premonitory symptoms having been manifested. Immediately the diagnosis has been made, that an ulcer of this kind has perforated the stomach wall, an operation for the relief of the condition ought to be carried out.

Some surgeons have suggested that, in certain forms of gastric ulcer, an operation should be performed before perforation has occurred, in order to avoid the dangers of general peritonitis. Owing, however, to the fact that only a small percentage of gastric ulcers cause perforation, and to the severity of the operation for the cure of a non-perforated ulcer, it does not seem advisable to adopt this method of treatment.

The symptoms of shock, which in all cases supervene imme-

FIG. 78.—Gastro-enterostomy: Posterior operation (Von Hacker's method).

diately after the occurrence of perforation, must be combated by the administration of stimulants, such as strychnine given hypodermically, in order that the patient may not be too collapsed to withstand the further shock due to the operation.

Position.—The patient is placed in the dorsal position on the operation table, the surgeon stands on the right side and his assistant on the left.

Operation.—The operation may be divided into several stages, namely :—

(a) *External incision.*—An incision is made half an inch to the left of the linea alba, commencing immediately below the lower border of the ensiform cartilage, and extends downwards towards the umbilicus for a distance of 3 or 4 in. This incision is deepened until the peritoneal cavity has been opened, all hæmorrhage from the parietal vessels being arrested.

(b) *Finding of stomach and perforation.*—The anterior surface of the stomach can usually be seen at the bottom of the wound.

The adjacent coils of small intestine, if they protrude, are held aside by packing with flat sponges. If a perforation has taken place, and the contents of the stomach have passed into the peritoneal cavity, it generally happens, when the peritoneum is incised, that gas and particles of food escape.

The stomach having been found, search is made for the perforation. This, in most instances, is situated either on some part of the anterior surface of the viscus, or in the vicinity of the lesser curvature. If it cannot be at once seen, the stomach is palpated with the finger, and often a localised hardness will indicate the region of the ulcer which has caused perforation. In order to examine the lesser curvature, it is necessary for the liver to be lifted up by the assistant. As the liver is lifted up, adhesions between its inferior surface and the stomach will often become manifest. The presence of adhesions of this kind usually indicates the seat of the perforation. If the perforation cannot be discovered on the anterior aspect, or in the region of the lesser curvature, it will be necessary to carefully break through the gastro-hepatic omentum on the left side of the portal vessels, and then examine the posterior aspect. A similar examination may be made by dividing the anterior lamina of the great omentum about half an inch below the greater curvature. This, in my opinion, is a better method.

Occasionally, when the perforation is on the posterior aspect of the viscus, its position may be located by passing the finger through the foramen of Winslow into the cavity of the lesser sac, and then palpating the posterior part of the organ.

When the perforation has been located by one of these methods, it must, if possible, be closed. Before doing this, the region of the perforation must be "carefully sponged" with an aseptic solution, so as to remove all stomach contents which may have escaped. If the aperture in the stomach wall is large, a tube should be passed through it, and all food washed out from the interior of the stomach by irrigation.

(c) *Closure of perforation*—The aperture is then closed by the insertion of a number of Lembert's sutures, each suture taking up the submucous, muscular, and serous coats only. If possible, that portion of the stomach which is the seat of the perforation should be brought into the parietal wound during the insertion of the sutures. All the sutures should be introduced before any are tied.

It is important to remember that the size of the perforation does not correspond to the size of the ulcer, and that, therefore, in order to avoid diseased tissue, the sutures must be placed at least half an inch to three-quarters of an inch clear of the margin of the aperture.

When the margins of the ulcer are indurated and irregular, it is advisable to excise the hardened portion before introducing the sutures. In this case the margins of the mucous membrane are united first by a continuous suture, and then the remainder of the coats as above. Care must be taken that each Lembert's suture takes up some of the submucous coat.

The sutures are now tied, their ends cut short, and the region of the perforation well sponged. The stomach is then dropped back into the peritoneal cavity. Occasionally it will be found impossible to close the aperture with sutures. In some of these cases it may be possible to close the aperture by stitching over it a piece of the great omentum. When this cannot be done, the margins of the perforation must be sewn to the parietal incision, so as to make a gastric fistula; or, failing this, a drainage tube must be passed down to the perforation, and the part of the peritoneal cavity around the tube packed with long strips of aseptic gauze, one extremity of each strip protruding from the external incision.

(d) *"Treatment" of peritoneal cavity*.—When the aperture in the stomach wall has been dealt with by one of the methods mentioned above, the sponges are removed from the peritoneum, and the entire cavity sponged with an aseptic solution, if there has been a general escape of stomach contents into the peritoneum. Care must be taken to remove all débris from the pelvis, and in order to do this it may be necessary either to

enlarge the incision in the abdominal wall, or to make a second one below the umbilicus. If the stomach contents have only contaminated the region of the perforation, it is not necessary to sponge the general peritoneum.

(e) *Establishment of drainage and closure of external wound.*—It is necessary, in most cases of perforation of a gastric ulcer, to drain the peritoneal cavity after the perforation has been closed. This is done by the insertion of one or two glass or rubber drainage tubes, which are passed through a part of the external wound which has been left open for the purpose. When the depths of the pelvis have been contaminated with stomach contents, it is advisable to pass a tube into this part.

The external wound is closed in part, or entirely, by the insertion of one or more tiers of sutures in the usual manner.

When the aperture of perforation has been shut off from the rest of the peritoneum by the presence of adhesions, it may be advisable to close the entire external wound, but this is of rare occurrence.

After-treatment.—The patient should not be fed by the mouth for several days after the closure of the perforation, but the strength should be maintained by the administration of nutrient enemata. Small quantities of ice or warm water may, however, be given by the mouth. The state of general nutrition of a patient who is suffering from a perforated gastric ulcer is usually good; hence, for the first few days, little food is required.

OPERATIONS UPON THE SMALL INTESTINES.

Closure of perforating wounds.—Perforating wounds of the small intestine may be made—(a) By the surgeon, as in the removal of an impacted gallstone or a foreign body; or for the relief of flatus, during an abdominal operation, when distended coils of gut hamper the proceedings or obviate the return of intestine to the abdomen; or (b) as the result of an injury, such as stab with a knife, a fall upon sharp railings, a gunshot wound, or a bayonet wound.

The wound may penetrate either the abdominal parietes or the thoracic wall and the diaphragm.

In order to locate the position of the perforation of the intestine, it is usually necessary to perform an abdominal section, either through the linea alba, or by enlargement of the original wound. It occasionally happens that a coil of intestine is protruded through the aperture in the parietes, and the perforation in it can be at once seen.

It is nearly always necessary in these cases, however, to examine the other coils of intestine, so as to be certain that a second perforation is not passed undetected.

When the wound has been discovered, the injured loop of intestine is brought through the parietal incision, and surrounded with warm aseptic sponges or towels, and the region of perforation well washed, so as to remove all dirt or intestinal contents. Often the mucous membrane will be found to be protruded through the aperture in the intestinal wall. An attempt should be made in every case to unite the margins of the mucous membrane with a continuous fine silk ligature. The perforation is again sponged clean, and the margins of the aperture in the muscular and serous coats approximated and fixed in apposition by a series of Lembert's sutures of fine silk, introduced about one-fifth or one-eighth of an inch apart. Care must be taken in the insertion of these sutures, that one is placed beyond each extremity of the aperture in the intestinal wall. If other perforations be present, they must be treated in a similar manner.

When all have been closed, the area of perforation is "sponged" with an aseptic solution, the injured coil or coils returned into the peritoneal cavity, and the wound in the parietes closed in the ordinary manner.

The after-treatment of these cases is similar to that mentioned in connection with "resection of the intestine," p. 86.

When the perforations are very large or numerous, it is usually necessary to remove the injured coil or coils according to the method which is described later.

Removal of a portion of intestine.—Removal of a portion of the small intestine is generally called "enterectomy," of the large intestine "colectomy."

Indications.—Excision, resection, or removal of a portion of the intestines is indicated in the following conditions, namely:—

(a) *Strictures.*—Strictures of the intestines, either simple or malignant, especially the latter. Simple growths of the intestines rarely cause obstruction which necessitates resection of the affected part, but occasionally such a procedure is called for. Malignant growths usually involve the large intestines, and when they can be localised, and there are no signs of secondary affections elsewhere, resection is indicated.

(b) *Gangrene of intestine.*—Gangrene of a portion of the intestine is usually due to some form of strangulated hernia; removal of the gangrenous portion is then necessary. The method of treatment, after the dead portion has been removed,

depends upon the situation of the diseased tissue, and the general condition of the patient. If the strength of the patient is good, or if the gangrenous portion is situated high up in the small intestine, anastomosis of the divided ends must be performed; whilst, if the condition of the patient is so serious that it is probable that a prolonged and severe operation will not be borne, the dead portion is removed and the open extremities of the divided gut fixed in the abdominal wound. If the patient survive this stage, the anastomosis and restoration of the canal can be effected at a later period.

(c) *Intussusception*.—Certain cases of intussusception in which the invaginated portion cannot be reduced, or gangrene has taken place.

(d) *Injuries*.—Those forms of injuries of the intestines where extensive laceration of the walls of the gut has taken place.

(e) *Tuberculosis*.—Some forms of intestinal tuberculosis, when the affection is localised to one portion of the alimentary tract, as in tuberculosis of the cæcum.

(f) *Adhesions*.—Occasional cases of fibrous stricture following an injury, and due to extensive and tight adhesions.

(g) *Fistulæ*.—Intestinal fistulæ which are not curable by less severe measures.

Varieties of operation.—A number of different methods of resection of a portion of the alimentary canal have been adopted by surgical operators. The most important may be divided into two distinct classes, namely:—

(a) Methods in which the approximation of the divided extremities is accomplished by means of some form of *suture*. Two forms of this operation will be described—(1) Union by *circular enterorrhaphy*; (2) union by *Maunsell's method*.

(b) Methods in which the approximation is accomplished with the aid of a *mechanical appliance*, such as a *Murphy's anastomosis button*, a *bone tube*, or a *bone bobbin*.

All these methods of union are available in what is called “end-to-end” anastomosis, but in some cases it is advisable to establish a lateral anastomosis or union, a result which may be accomplished by one of the above methods, or can be readily brought about with a contrivance known as *Senn's decalcified bone plates*. The method of using *Senn's plates* will be considered in the operation of “lateral anastomosis,” p. 87.

Special instruments.—Scalpel with a long narrow blade like a finger knife, intestinal clamps, Murphy's “anastomosis button,” a bone tube, or a bone bobbin (whichever it is wished to use).

Position.—The patient in nearly all cases is placed in the

dorsal position, but the position of the operator depends upon the situation of the parietal incision. The chief assistant stands directly opposite the surgeon, and the second assistant on his left hand.

Operation.—In all cases of resection of the intestines, the actual operation may be divided into five stages, which are the following :—(a) Parietal incision ; (b) finding of the diseased portion of intestine, and bringing it out through the wound in the abdominal wall ; (c) removal of the affected piece ; (d) union of the divided ends of the intestine ; (e) closure of the external wound. The first two and the last stages are similar in all forms of intestinal resection, but stages *c* and *d* differ in details, according to the individual procedure which is being adopted. The first two stages, *a* and *b*, will be first described, then the modifications which occur in stages *c* and *d*, and finally the method of closure of the external wound.

(a) *Parietal incision.*—The situation of the incision in the parietes depends upon the locality of the tumour or the part of the intestine which it is intended to remove. As far as possible, it ought to be made half an inch to one side or other of the linea alba, or directly over the tumour. In the case of a strangulated hernia, it is not possible to decide whether the gut will require resection until it has been exposed through the usual hernial incision ; and when it is found to be gangrenous, the incision is enlarged sufficiently to enable the coil of gut to be brought out of the wound, and to allow of its return after the resection has been performed. Usually an incision from 3 to 4 in. in length will be long enough to enable the surgeon to readily perform all the manipulative procedures which are requisite.

(b) *Finding of diseased portion of intestines, and bringing it out through the wound in the abdominal wall.*—The fingers of the right hand are introduced into the peritoneal cavity, and the affected portion of gut is sought for ; and, when found, it is brought out through the external wound and surrounded with large flat sponges which have been wrung out of a warm antiseptic solution, preferably of boracic acid. If there are any adhesions which hold down the affected coil or loop, they are either broken down with the fingers or they are tied in two places with silk ligatures, and divided. The intestine having been delivered in this manner, the contents are forced onwards with the fingers until the lumen of the affected part is quite empty. Two intestinal clamps are taken and applied to the intestine, 2 in. above and below the lines where it is intended

to make the section. If these clamps are placed too near the lines of section, they interfere with the insertion of the sutures, and with the application of measures which have for their object the asepticity of the area of operation.

In cases of malignant disease, it is advisable to examine the mesentery for enlarged lymphatic glands, which, if found, must be removed.

(c) *Removal of the affected piece.*—The intestinal tube is divided transversely to its long axis and well beyond the diseased tissue. This can be done, either with strong scissors, or, better, by transfixing the mesentery close to the intestine with a long narrow-bladed scalpel, and cutting outwards. When this has been done, the portion of mesentery which is

FIG. 79.—Enterectomy: Lines of incision in bowel and mesentery.

attached to the separated piece of intestine is divided along the line of attachment of the gut (Fig. 79). As this is done hæmorrhage from many small blood vessels occurs, and is arrested by picking up each bleeding point with a pair of pressure forceps.

The advantage of this method of division of the mesentery is, that a better blood supply is left than when a wedge-shaped piece is removed. If, however, the disease or growth has involved the mesentery, it must be removed by making a wedge-shaped incision, as shown in Fig. 80. In Maunsell's method of operation, also, a wedge-shaped piece must be removed. When all hæmorrhage has been arrested, and the cut ends of the intestine well washed with an aseptic solution, approximation and union can be performed.

(d) *Union of the divided intestine*—(I) *By circular enterorrhaphy*.—Four sutures are first inserted so as to hold the margins of the divided intestine in apposition and ensure exact approximation. The first one is passed at the mesenteric attachment, the second at the convexity of the gut opposite the attachment of the mesentery, and the third and fourth half-way between the mesentery and the convex border, one on each side. Each of these sutures is made to transfix the mucous and submucous coats, and is left long. These are given to the assistant to hold, whilst the surgeon inserts a series of similar sutures which shall approximate and fix in apposition the mucous and submucous coats for the entire circumference of the bowel. When this has been done, all the sutures are cut short except

FIG. 80.—Enterectomy: Lines of incision in bowel and mesentery, when a V-shaped piece is removed from the latter, as in Maunsell's operation.

the first four, which are left long to help in the insertion of the next series. A circle of Lembert's sutures is now inserted about one-sixth or one-eighth of an inch apart. Each long suture is cut short as soon as the neighbouring Lembert's sutures have been inserted. These Lembert's sutures are introduced according to the method shown in Fig. 50, a second tier being added if necessary. When the complete circle has been introduced and tied, the approximation of the intestine is finished, and nothing remains but to fold the mesentery in the form of a "pleat" and fix it as in Fig. 87. If there is any doubt as to the security of the stitches in the part of the intestine near the mesentery, it may be advisable to stitch the mesentery over this portion, in order to give a little extra security. In most cases, however, this is not requisite. The

line of approximation of the two ends of intestine is now carefully washed, together with any soiled portion of peritoneum, the clamps are removed, and the gut returned into the peritoneal cavity.

(2) *By Maunsell's method.*—The portion of the intestine which it is wished to remove, together with a V-shaped piece of the mesentery, is detached, according to the method shown in Fig. 80. This having been done, two sutures, one at the mesenteric attachment and the other at the convex border, are

FIG. 81.—Enterectomy (Maunsell's operation): Method of insertion of two long sutures, after the segment of gut has been removed and before invagination. The manner of insertion of sutures into the mesentery is also shown.

inserted as in Fig. 81, and the ends left long. Next, an incision is made in the long axis of the bowel on the convexity, as in Fig. 81. The length of this incision varies with the calibre of the gut which is being operated upon, but in every case the extremity of the incision nearest to the divided end of the intestine is 1 in. beyond it. This incision should be made in that portion of the bowel which has the larger calibre. A pair of pressure forceps is passed through this longitudinal incision, and the two long threads, *a* and *b*, are pulled through, as in Fig. 81, and the smaller segment of the gut invaginated within the larger.

Next, the margins of the two divided ends of intestine are fixed in apposition by the insertion of a number of simple interrupted sutures, each one transfixing all the coats of the bowel. Maunsell advises that a long straight needle should be

passed through both walls of the bowel at the same time, and the thread hooked up from the interior of the gut, and cut

FIG. 82.—Enterectomy (Maunsell's operation). Third stage, showing the bowel invaginated and ready for suturing.

across. It is better, however, to pass each suture separately, and to perforate the walls of the gut from the serous to the mucous surface. When all these sutures have been inserted,

FIG. 83.—Enterectomy (Maunsell's operation). Operation according to Maunsell's method completed.

a. Line along which series of Lembert's sutures should be inserted.

tied, and the ends cut short, the area of operation is well washed, so as to render it aseptic, and then the sutured portion or intestine retracted, as in Fig. 83. The longitudinal cut is

again cleansed and closed by the insertion of five or six Lembert's sutures. The margins of the incision in the mesentery are next united by sutures, and the approximation and union is completed. This is Maunsell's own operation; but in my opinion it is safer and better to unite the line of union *a*, in Fig. 83, by a circle of fine silk sutures, introduced after Lembert's method.

The coil of intestine and the exposed peritoneum having been cleansed from all blood and intestinal contents, the bowel is returned into the abdomen.

(3) *By the aid of Murphy's "anastomosis button."*—The diseased portion of intestine having been removed, according to the method shown in Fig. 79, all bleeding from the mesenteric border is arrested. Next, the exposed lumen of the gut and the margins of the divided ends are thoroughly washed with an antiseptic solution. A "purse-string" suture is inserted around the margin of each divided end, in the manner illustrated in Fig. 84. Next, the two halves of the anastomosis button are taken, and each grasped with a pair of pressure forceps. The female half of the "button" is placed in the lower half of the gut (if this is known), the "purse-string" suture is tied, and the ends cut short. The male half is then placed in the upper segment of the gut, and the suture tied in a similar manner. The pressure forceps are now removed, and the two ends of the gut pressed to-

FIG. 84.—Enterectomy (Murphy's operation). Method of inserting "purse-string" suture into divided extremity of gut.

- a.* Mesenteric border of bowel.
- b.* Free border of bowel.
- c.* Mesentery.

gether so as to cause locking of the "button." Fig. 86 shows both halves of the "button" inserted, and the "purse-string" sutures cut short before the ends are approximated, and Fig. 87 their appearance when the union has been completed.

Next, the mesentery is folded in the form of a "pleat," and fixed by the insertion of a few points of interrupted suture. Murphy does not advise any further suturing, but in my opinion it is advisable to fix the margin of the approximated serous surfaces by the insertion of a circle of fine silk sutures after Lembert's method. The pressure of the "button" upon the included margins of the intestine causes a pressure-gangrene, which sets free the button itself and allows it to pass along the alimentary canal, and be passed per anum. The insertion of a row of Lembert's sutures gives additional support, and helps to prevent giving way of the line of union in the early stages.

Each of these sutures should pierce only the serous, muscular, and submucous coats. One of the objections to the use of these "buttons" is their small lumen. If they are used in cases of strangulated hernia, a condition which does not allow the intestine to be emptied by purgatives before operation, there is always a possibility of any large piece of

FIG. 85.—Murphy's anastomosis "button."

FIG. 86.—Enterectomy (Murphy's operation): Segment of gut removed, and two halves of "button" inserted and ready for approximation.

indigestible food becoming impacted there and causing a fresh attack of obstruction.

(4) *By the aid of a bone tube or a bobbin.*—The methods of operation in these cases are very similar, but decalcified bone possesses the advantage of becoming readily absorbed under the influence of the intestinal secretions. Figs. 88 and 89 are illustrations of these contrivances.

When the two divided ends of the intestine have been freed from all contamination with blood and intestinal contents, a continuous suture, which pierces the entire wall of the gut, or a circular ligature, which surrounds it, is inserted and tied, by which means the divided ends are fixed in close approximation. Next, the serous surfaces of the two portions of intestine in the region of section are united by the insertion of a circle of Lembert's silk sutures. The treatment of the mesentery is similar to that mentioned in the previous operation.

FIG. 87. — Enterectomy (Murphy's operation): Appearance of intestine when the operation is completed. The mesentery opposite the resected portion is folded upon itself, and fixed by a few points of suture.

(e) *Closure of the external wound.*—When the loop of intestine has been returned into the abdominal cavity, and care taken that the bowel is not twisted upon itself, the external incision is closed. This is carried out in the ordinary manner, by the insertion of one or more tiers of interrupted sutures. Drainage is not usually required.

After-treatment.—The after-treatment of a patient from whom a portion of the alimentary canal has been removed, has for its object the maintenance and improvement of the patient's general condition, combined with rest to the alimentary canal. It is advisable to give small quantities of opium by the mouth every few hours, and to see that the food is liquid, easily digestible,

FIG. 88.—Decalcified bone tube.—BAILEY.

FIG. 89.—Decalcified bone bobbin.—ROBSON.

and peptonised if possible. If these points are attended to, few complications will arise.

For the first two or three days it may be advisable to administer nutrient enemata.

Lateral intestinal anastomosis.—In this operation two loops

of intestine are fixed in apposition in such a manner that the convexities of the coils are close together.

Usually lateral anastomosis is established by means of sutures, or with the aid of an anastomosis button, as in the method described for gastro-enterostomy, but it may be effected by the use of decalcified bone plates (Senn's plates).

Indications.—This procedure is adopted chiefly for the relief of those cases of stenosis of the gut unsuited to direct treatment, by removal of the cause of stricture or obstruction.

Operation.—The abdomen having been opened by a median or other incision, the seat of obstruction in the alimentary canal is sought for. A coil of intestine is selected above and below the seat of obstruction, and a short distance from the diseased segment. Each loop is emptied of its contents, by passing it between the fingers. Intestinal clamps are applied to the upper

FIG. 90.—Senn's decalcified bone plate for operation of lateral intestinal anastomosis.

FIG. 91.—Lateral intestinal anastomosis: Two coils of intestine, partly approximated with Senn's plates.

A. Closed end of intestine.

The interior of each loop of intestine is cleaned out by careful sponging. Next, the plates are introduced already threaded, and the lateral or fixation sutures, and the end or apposition sutures tied. The peritoneal surface of the gut which overlies the plates is scarified with a needle or the point of a scalpel, and the two openings brought into approximation.

The sutures of the two plates are now tied, and the ends cut

and lower extremities of each loop, as in "intestinal resection." The exposed intestines are well surrounded with warm sterilised towels, and then an incision long enough to readily allow the introduction of the "bone plate" is made on the convexity of the bowel opposite the mesenteric attachment.

short. The serous membrane over the margins of the approximated plates is united with a few points of interrupted suture, the intestine washed free from all traces of intestinal contents, and returned into the abdomen. The external wound is then closed. Fig. 90 is an illustration of a "bone plate," and Fig. 91 of two coils of intestine with plates inserted and about to be brought into apposition with the aid of this mechanical appliance.

The technique of this operation is complicated, and the results do not appear to be better than those which have been obtained by careful suturing, or after the use of an "anastomosis button" or "tube."

Formation of an artificial anus, or creation of an intestinal fistula.—It only rarely happens that it is necessary to establish an artificial communication between the lumen of the small intestine and the surface of the body.

Indications.—(a) Acute intestinal obstruction of some part of the small intestine which cannot otherwise be relieved.

(b) Strangulated hernia, in which the herniated portion of gut has become gangrenous, and the condition of the patient will not allow of the performance of an intestinal anastomosis.

Special instruments.—Trocár and cannula, or aspirator, and needles.

Position.—The patient is placed in the dorsal position on the operation table, whilst the operator stands on whichever side is the more convenient, and the assistant stands opposite to him.

Operation.—In cases of strangulated hernia, the incision will necessarily be made in one of the hernial regions, and in other cases of intestinal obstruction it will usually be made near the linea alba or the linea semilunaris, according to the supposed position of the obstruction.

The loop of intestine which it is proposed to open is brought into the parietal wound, and is fixed to the margins of this by the insertion of a series of sutures, each suture passing through the serous, muscular, and submucous coats of the intestine, and then through the serous, fascial, and cutaneous strata of the abdominal wall. In practice it will usually be found advisable to open the intestine and allow the escape of the fluid or gas with which it is distended, before an attempt is made to attach it to the abdominal wall; or, in the case of gangrene, it may be requisite to remove the dead portion before this is done. The exact method of inserting the sutures is described in connection with "Inguinal Colotomy" (p. 102).

Perforated duodenal ulcer.—In the majority of instances the operation requisite for the treatment of a perforated duodenal ulcer is similar to the procedure which has been described in detail in connection with “perforated gastric ulcer,” p. 75. When a definite diagnosis of perforation of a duodenal ulcer has been made, the abdomen should be opened by an incision 3 to 4 in. long above the umbilicus, and about 1 in. to the right of the middle line. In doubtful cases the incision should be half an inch to the right of the middle line. When the aperture of perforation has been located—it is usually in the first part, rarely in the second or third—it is closed by sutures, as in the case of a similar ulcer of the stomach. It should be remembered that perforation may take place into the lesser peritoneal cavity, in which case an abscess will develop in this space, which may extend to the subphrenic space, and cause the formation of a subphrenic abscess.

Perforation of typhoid ulcer.—Perforation of a typhoid ulcer into the general peritoneal cavity gives rise either to septic peritonitis or to the development of a localised intra-peritoneal abscess. The former result of perforation is very much more frequent than the latter. During recent years many operations have been done for the closure of the perforation in the bowel wall, and for the treatment of the consequent peritonitis. Personally, I have performed the operation five times; two patients recovered and three died. A collection of the recent cases which have come under my observation shows that from 25 per cent. to 40 per cent. of cases recover, the higher percentage being obtained when the operation has been carried out within twelve hours from the time of occurrence of perforation.

Indications.—All cases in which the occurrence of a perforation of a typhoid ulcer of the intestine has been diagnosed, should be submitted to a surgical operation as soon as possible after the occurrence of the perforation. This operation has for its object, finding and closure of the perforation, and cleansing and drainage of the contaminated area of peritoneum.

Position.—The patient is placed in the dorsal position, the lower limbs being slightly drawn upwards by flexion at the knee and hip. The operator stands on the right side and the chief assistant on the left.

Operation.—The operation can be divided into four stages:—

(a) *Parietal incision and opening of peritoneal cavity.*—A vertical incision is made a little to the right of the middle line, which commences at the lower margin of the umbilicus and extends downwards for 3 in., or even more if the abdominal

walls are thick. The different strata of the abdominal wall are cut through in the usual manner, and the peritoneal cavity opened.

(b) *Finding and closure of perforation in intestine.*—When the peritoneal cavity has been opened, the forefinger is passed inwards and the peritoneum on the right side of the incision carefully palpated, in order to detect if any adhesions between a coil of intestine and abdominal wall are present. It occasionally happens that the intestine at the seat of perforation becomes adherent to the deep aspect of the anterior abdominal wall. If no adhesions are met with, the margins of the wound are strongly retracted, and the lower portion of the ileum is brought into the parietal wound and carefully examined, in order to locate the position of any perforation which may be present. If the lower part of the ileum does not show any perforation, the cæcum, vermiform appendix, and adjacent portion of the ascending colon are examined with the same object. Failing detection of an ulcer here, the sigmoid flexure is felt for in the left iliac fossa and pelvis, brought into the wound and examined. Practically all cases of perforation of ulcers of the intestine in typhoid fever have been found in the lower portion of the ileum, in the ileo-cæcal region, or in the sigmoid flexure. When the perforation has been located, it is closed by the insertion of a series of silk sutures by Lembert's method. The line of sutures should be placed transversely to the long axis of the bowel. Care must be taken, in inserting the sutures, to place them beyond the margin of the perforated ulcer, and at the same time not to perforate a second ulcer in the immediate neighbourhood. The position of other ulcers can be distinguished, since the position of each is indicated by a discoloured area on the wall of the gut. If necessary, a second tier of sutures may be inserted, when there is any doubt as regards the complete closure of the perforation.¹ When the perforation has been satisfactorily closed by sutures, the portions of intestine immediately above and below the region of the perforation are carefully examined, in order to detect the existence of a possible second perforation.

(c) *Treatment of peritoneal cavity.*—The region of the sutured intestine should be carefully sponged, first with an antiseptic solution and then with warm saline solution, and all contaminated areas of peritoneum should be treated in a similar manner, special attention being given to the recto-vesical pouch. If the patient is very collapsed at the end of the operation, it is advisable to leave a quantity of hot saline solution in the peritoneal cavity.

(d) *Partial closure of external wound and establishment of drainage.*—When there has been only slight contamination of the peritoneal cavity, and consequently limited peritonitis, a gauze drain should be passed down to the region of the sutured intestine, and the remainder of the wound in the abdominal parietes closed. When a considerable area of the peritoneum has been contaminated by intestinal contents, or there is extensive peritonitis, a large rubber drainage should be passed down to the bottom of the recto-vesical pouch or the right iliac fossa, whichever happens to offer the best drainage. The other parts of the abdominal wound are closed by sutures.

OPERATIONS UPON THE LARGE INTESTINE.

Removal of the vermiform appendix.—The vermiform appendix is attached to the postero-internal aspect of the cæcum, a short distance, usually about half an inch, below the lower border of the ileo-cæcal valve. The length of the appendix varies considerably. It usually measures 3 or 4 in., but in some cases it is not more than 2 in. long, whilst in others it may be even 10 in. The position of the free extremity varies: usually it hangs over the pelvic brim in front of the commencement of the external iliac vessels, and then has a distinct mesentery formed by a double fold of peritoneum, in which is a small artery, the vermicular twig from the ileo-cæcal branch of the superior mesenteric artery. The corresponding vein is a tributary of the portal vein. In other cases the appendix is located behind some part of the cæcum, or it may be situated in the iliac fossa immediately above the middle part of the Poupart's ligament of the right side.

Indications for removal.—Removal of the vermiform appendix is indicated in the following circumstances, namely—

- (a) Perforation of the appendix.
- (b) Ulceration of the interior of the appendix, leading to a collection of pus in the interior, to localised destruction of its wall, and perforation.
- (c) Cases of relapsing appendicitis, in which each successive attack is worse than the previous one, or in which serious inconvenience is caused.
- (d) Those pathological conditions which necessitate removal of the cæcum.

Position.—The patient is placed in the dorsal posture, and near the right edge of the table; the surgeon stands on the right side, opposite the iliac region, and the assistant on the left.

Operation.—Removal of the vermiform appendix may be divided into three stages, namely—

(a) *Parietal incision.*—An imaginary line is drawn from the anterior superior iliac spine of the right side to the umbilicus, and a point a third of the distance from the iliac spine selected. When there is reason to believe that many adhesions exist, the selected point should be half-way between the anterior superior iliac spine and the umbilicus. An incision 3 in. in length is made at right angles to the imaginary line, and passing through the selected point. One-third of this incision is above the line, and two-thirds below it. Care must be taken, however, not to prolong the lower limit of the incision as far as the deep epigastric vessels. The skin and fasciæ are divided, and the

FIG. 92.—Removal of vermiform appendix. Position of patient and line of parietal incision.

superficial aspect of the external oblique muscle exposed. Next, this muscle is divided parallel with the direction of its fibres for the entire length of its exposed portion. This division is commenced with the scalpel and completed with the fingers. The margins of the incision in the external oblique are now held widely apart with retractors, so as to fully expose the fibres of the internal oblique muscle. These are separated and divided parallel with the direction of the fibres in a manner similar to that adopted for the external oblique. The line of division of the internal oblique is almost at right

angles to that in the external oblique. Next, the fibres of the transversalis abdominis are separated in a like fashion. They will be found to be practically parallel to those of the internal oblique. The margins of the apertures so made in the muscular strata are held widely apart with strong retractors, and then the fascia transversalis and parietal peritoneum are divided in the line of the skin incision. The abdominal cavity is thus opened.

The advantage of opening the abdominal cavity in this manner is, that the patient is very much less liable to the development of a ventral hernia at the seat of the parietal incision afterwards, owing to the fact that little scar tissue is produced, very few muscular fibres are divided, and the incisions through the different planes of the abdominal wall are not opposite one another.

(b) *Finding, separation, and removal of appendix.*—The coils of the small intestine and the lower margin of the great omentum are pushed over towards the left, and kept there by packing with a large flat sponge. If no adhesions are present, the cæcum is lifted upwards and towards the right, and then the appendix will be partially or entirely exposed. The appendix having been found by the method mentioned above, its mesentery is defined. When this has been done, the mesentery is transfixed at its base, close to the cæcum, with a needle armed with a silk ligature. This ligature is tied, and

FIG. 93.—Removal of vermiform appendix. Line of incision through serous and fibrous coats, with a "cuff" of serous and fibrous coats turned back.

FIG. 94.—Removal of vermiform appendix. "Cuff" of serous and fibrous coats dissected back, and mucous coat ligatured close to its attachment to cæcum.

the line of attachment of the mesentery to the appendix divided with a pair of scissors. By this means the appendix is freed from its connections, except where it is attached to the cæcum. The apex of the appendix is seized with pressure forceps, and with the scalpel the serous and muscular (or fibrous) coats are divided in a circular manner, about two-thirds of an inch from the cæcum, and a "cuff" or "flaps" of tissue stripped back until the cæcum is reached (Figs. 93 and 94). Care must be taken not to divide the mucous membrane during this procedure. A fine silk ligature is then tied around the mucous membrane, just beyond its junction with the cæcum; the tube of mucous

membrane immediately distal to the ligature is cut across with scissors, and the appendix removed. The ligature which surrounds the mucous membrane of the stump of the appendix is cut short, and the stump itself inverted into the cæcum. The "cuff" or "flaps" of peritoneal and fibrous coats is pulled over the base of the inverted stump, and sewn up by the insertion of two or three points of Lembert's suture.

If, owing to adhesions or inflammatory changes, it is not possible to dissect back a "cuff" of serous and fibrous coats, a silk ligature is applied around the entire appendix at its junction with the cæcum, and the structure removed. Next, the mucous

over stump of appendix.

membrane in the middle of the stump is either cauterised or well washed with an antiseptic, and then the stump is inverted into the cæcum and held in that position by bringing the adjacent portions of the serous and muscular coats of the cæcum together, by means of two or three fine silk Lembert's sutures.

(c) *Closure of the external incision.* — The region of operation is well washed with an aseptic solution, especially where there has been any soiling of the peritoneum, the sponges are

removed, and the external wound closed by the insertion of one or more tiers of sutures, according to the method described on p. 47.

When the affection of the appendix has resulted in the formation of a localised collection of pus, the overlying portion of the peritoneal cavity will often be obliterated by adhesions, and the external incision may be made through the most prominent part of the swelling, care being taken to avoid opening the peritoneum.

Suppurative appendicitis.—Two essentially different conditions, as regards the character of the surgical procedures to be adopted, are met with in cases of suppurative appendicitis.

The first class of case comprises those patients in whom an attack of appendicitis has given rise to a localised abscess in the region of the vermiform appendix, and generally limited to the lower portion of the right iliac fossa. This abscess may either be a localised suppurative peritonitis around a diseased appendix, in which the adjacent portion of the peritoneum is cut off from the abscess by the development of a number of fibrinous adhesions; or it may be a collection of purulent matter behind the cæcum, appendix, and parietal peritoneum, and in the fascial layers of the right iliac fossa in front of the ilio-psoas muscle. Clinically it is not often possible before commencing an operation to make an exact diagnosis as to whether an individual case belongs to one or other of these varieties. The second class of case includes those patients in whom a suppurative appendicitis has given rise to perforation of the wall of the vermiform appendix, extension of the purulent contents to the general peritoneal cavity, and establishment of general suppurative peritonitis.

Indications for operation.—Whenever the symptoms and physical signs present in a patient, presumed to be suffering from appendicitis, point either to the development of a localised abscess, or to the occurrence of perforation of the vermiform appendix and establishment of general peritonitis in the region of the right iliac fossa and the pelvis, an operation should be carried out without delay. The object of this operation is to expose the abscess cavity, if present, evacuate its contents and establish free drainage, so as to avoid, as far as possible, spread of the suppurative process to other parts of the peritoneum or adjacent abdominal viscera. When the general peritoneum has been invaded, the region of the appendix and its associated abscess in the right iliac fossa must be exposed and dealt with, and then the parts of the peritoneum which have been invaded, freed from purulent matter and efficiently drained. In the latter class of case it is often necessary to make a second incision at or near the middle line, in order to satisfactorily evacuate all the purulent collection and thoroughly drain the contaminated areas.

Operation.—The operation may be divided into several stages—

(a) *External incision and division of abdominal wall.*—Before deciding upon the exact line of incision, the region of the right iliac fossa should be carefully palpated, in order to locate the position of the abscess, and also any point where it may be adherent to the deep aspect of the anterior abdominal

wall. If adhesions, or any specially prominent fluctuating area, can be made out in this manner, the incision should be made directly over them. In other cases, an incision $2\frac{1}{2}$ to 3 in. long is made, parallel with and about two-thirds of an inch above the outer half of Poupart's ligament and the anterior portion of the iliac crest. The different strata of the abdominal wall are successively divided in the line of the skin incision until the extra-peritoneal layer is exposed. This can usually be recognised in suppurative cases, by its œdematous condition or the presence of flakes of fibrinous lymph. An ascending branch of the deep circumflex iliac artery will usually be cut, as it lies between the internal oblique and the transversalis. When cut, this vessel

should be at once ligatured, as it bleeds freely, and so causes obstruction to a free view of the area of operation.

FIG. 96.—Position of incision in suppurative appendicitis causing a localised abscess.

(b) *Opening and evacuation of the abscess cavity and its connections.*—When the extra-peritoneal tissue has been laid bare, the bottom of the wound is carefully examined with the forefinger, in order to detect the exact locality of the purulent collection. If it lies underneath the exposed area, the parietal peritoneum should be carefully incised so as to avoid opening the cæcum, in those cases where this viscus is attached to the

deep aspect of the anterior abdominal wall by fibrinous adhesions. The abscess cavity can often be opened by carefully scratching away the fibrinous lymph and sodden and œdematous peritoneum with a probe-pointed director. When the abscess cavity appears to be located behind the peritoneum and in the fascial layers of the iliac fossa behind the cæcum, the parietal peritoneum should be separated by careful dissection from the fascia transversalis and iliac fascia, until it can be opened without laying bare the general peritoneal cavity. The abscess cavity having been opened by one of these methods, its contents are evacuated and its interior thoroughly exposed to view by well retracting the margins of the external wound. Its walls are sponged dry, and any local prolongations or connections opened up by the finger, and their contents evacuated.

Care must be taken during these manipulations and investigations, that adhesions which may be present, and cut off the abscess cavity from the general peritoneal cavity, are not broken down or separated. When no adhesions exist, the contents of the abdomen, such as coils of small intestine or portions of the great omentum, are carefully protected by flat sponges or cellular pads, soaked in an antiseptic solution. The majority of localised appendicular abscesses in the right iliac fossa have prolongations into the adjacent part of the pelvis; and in those cases in which suppuration is not localised, the bottom of the recto-vesical pouch will almost always be found to contain a collection of purulent matter. Hence, in dealing with these cases, especial attention must be directed to the condition of affairs in the right side and bottom of the pelvis.

(c) *Treatment of the vermiform appendix.*—When the vermiform appendix is seen lying at the bottom of the abscess cavity, and to be readily removable, this should always be done, provided the removal can be carried out without opening up the general peritoneal cavity, and causing infection of the peritoneum. When it is firmly bound down to adjacent structures by adhesions, and it is thought that removal will involve opening up the general peritoneum and infection of it, it is better not to attempt it, but to wait until a more favourable period. It is not possible, however, to lay down exact laws on this point, as each individual case requires to be judged on its merits. Whenever the abscess cavity communicates with the peritoneum, and is not shut off by adhesions, then in all these cases the vermiform appendix—the actual cause of infection of the peritoneum—must be sought for and removed. When found, the appendix is separated from its surroundings by breaking down or cutting through adhesions until its attachment to the cæcum is exposed, the mesentery of the appendix being transfixed and ligatured if necessary. The actual separation of the appendix from the cæcum is similar to that described on p. 93. When the appendix is removed from the bottom of an abscess cavity, it is sufficient to separate it from its surroundings, encircle its base with a silk ligature, and cut away everything distal to the point of application of the ligature.

(d) *Treatment of the adjacent peritoneum.*—In those cases in which the suppurative affection of the vermiform appendix has given rise to a localised peritonitis within the right iliac fossa, and this is cut off from the general peritoneal cavity by the establishment of adhesions, the cavity should be thoroughly

drained by the insertion of one or two moderately large red rubber drainage tubes, in which holes have been cut in the parts which actually lie within the abscess cavity. When there are prolongations into the adjacent portion of the pelvis, or upwards into the upper part of the iliac fossa, rubber drainage tubes must be passed to the limits of the suppuration area. If there are no adhesions, and general peritonitis has been established, after evacuation of all purulent fluid, the infected areas should be sponged as far as possible with an antiseptic solution, and then rubber drainage tubes inserted, one into the iliac fossa and the region from which the vermiform appendix has been removed, and one to the bottom of the recto-vesical pouch.

When the patient is much collapsed after an operation of this kind, and there is extensive infection of the peritoneum, it is advisable to sponge or locally irrigate the iliac fossa and pelvis with hot salt solution, and to leave a quantity of this fluid in the pelvic cavity.

(e) *Closure of external wound.*—Only the extremities of the external wound should be closed by sutures, the remainder being left open for the exit of the drainage tubes and for insertion of any gauze packing which may happen to be requisite. It will occasionally be found necessary, in the latter class of cases, to make a second incision in the abdominal wall. This is generally made in the middle line and below the umbilicus. It allows the surgeon more readily and effectively to deal with suppurative affections within the pelvic cavity, and to establish better drainage from these areas.

Excision of the cæcum.—In excision of the cæcum, it is also usually necessary to remove a portion of the lowest part of the ileum. The vermiform appendix is attached to the cæcum, and hence is removed along with it.

Indications.—Certain cases of tuberculosis of the cæcum, when the disease is localised to this portion of the intestine; and primary malignant growths, which have not involved adjacent structures.

Removal of the cæcum may also be necessary in cases of inveterate fæcal fistula communicating with the interior of this part of the gut; and in occasional cases of cæcal hernia, when inseparable adhesions with the hernial sac have formed.

Position.—The patient is placed in the dorsal posture, near the right side of the table. The operator stands on the right side, and the assistant on the left.

Operation.—The operation of removal of the cæcum may be divided into stages.

(a) *Parietal incision.*—An imaginary line is drawn from the anterior superior spine of the ilium to the umbilicus; this is bisected, and an incision 3 to 4 in. long made at right angles to the imaginary line, one-half being above, and the other half below, the selected point. The incision is deepened until the peritoneal cavity has been opened.

(b) *Finding, separation, and removal of cæcum.*—The coils of small intestine and the lower portion of the great omentum are pushed upwards out of the way, and held there by packing the peritoneal cavity just above and internal to the right iliac fossa with flat sponges. This having been done, the cæcum will be exposed as it lies in the right iliac fossa. The last 3 in. (or more, if necessary) of the ileum is exposed. An intestinal clamp is then placed on the ileum 3 in. above the ileo-cæcal valve. The contents of the portion of the ileum below the clamp are forced with the fingers into the cæcum, and a pair of pressure forceps placed on the ileum at its junction with the cæcum.

With a pair of scissors or a long-bladed scalpel the ileum is divided immediately above the pressure forceps, and then the peritoneum, which is reflected from the iliac fossa to the cæcum, is divided by a series of snips with the scissors. As the cæcum is freed in this manner, it is lifted up from the iliac fossa, and all bleeding

FIG. 97.—Excision of cæcum.
Line of parietal incision.

vessels are seized with pressure forceps, and tied. When the cæcum and diseased portion of the ascending colon have been sufficiently separated (that is, when the limits of the disease have been passed), an intestinal clamp is placed on the ascending colon about 2 in. above the proposed line of section of the bowel. A second clamp or a pair of pressure forceps is then placed on the colon at the line of section, the intestinal contents being previously forced into the cæcum or onwards into the distal part of the colon. The ascending colon is now divided transversely immediately above the clamp nearest to the cæcum, and the cæcum, together with the vermiform appendix and the adjacent parts of the ileum and ascending colon, removed. When all hemorrhage has been arrested by ligature, the field of operation is well sponged out, and especial care taken to disinfect the cavities of the ileum and colon beyond the clamps.

(c) *Union of the divided ends of ileum and colon.*—The anastomosis of the ileum and colon is effected by one of the methods described in connection with “resection of small intestine.”

The same precautions must be observed as in dealing with the small intestine. Some surgeons have advised that the free end of the colon should be sewn up, and then the extremity of the ileum implanted in the lateral aspect of the ascending colon a short distance above its divided end. This method does not appear to present any advantages over end-to-end anastomosis.

When the union of the two portions of the intestine has been effected, all the sponges are removed from the peritoneal cavity, and the contaminated area well washed with an aseptic solution.

(d) *Closure of the external wound.*—This is effected in the usual manner.

Intussusception.—*Indications.*—An operation for the relief of this condition ought to be immediately carried out in all cases in which the diagnosis is apparent and efforts at digital reduction of the tumour have failed. The position of the intussuscepted portion can generally be made out by palpating the abdomen and feeling an elongated tumour in the line of the colon, by rectal examination, or by a bimanual examination with the finger in the rectum.

Operation.—An incision $2\frac{1}{2}$ in. long is made one-third above the umbilicus and two-thirds below it, and a little to the right of the middle line. The abdominal cavity being opened, the forefinger is first passed into the right iliac fossa and then along the course of the colon until the tumour caused by the intussusception is located. When the tumour has been found, it is brought into the abdominal wound. Combined gentle traction and manipulation of the distal portion of the swelling are then carried out, and the tumour reduced. Much assistance may often be obtained in reduction, by taking the tumour between the two hands and exerting firm pressure upon it for a few minutes, so as to reduce the blood and serum in it. Attempts at reduction—traction on the entering piece and manipulation of the distal end—will then, in nearly all cases, be successful. When the gut is gangrenous, resection of the dead portion and end-to-end anastomosis should be carried out, as described in pp. 79 *et seq.*

When reduction has been successfully accomplished, the gut is returned into the abdomen and the parietal wound closed by tiers of sutures.

Resection of the large intestine.—The methods which are adopted for the removal of portions of the large intestine are

similar to those which have been already described in connection with the surgery of the small intestine.

The chief indications for removal of portions of the large intestine are—localised malignant growths, gangrene in connection with strangulated hernia, severe lacerations, and some forms of severe localised ulceration.

Colotomy—Inguinal colotomy.—Inguinal colotomy has for its object the creation of a fistulous communication between the lumen of the colon and the surface of the abdomen in the inguinal region. The operation is usually performed on the left side, the sigmoid flexure becoming the seat of the fistula; but occasionally the artificial anus is made on the right side, and the ascending colon is opened.

Indications.—Inguinal colotomy may be performed, either as a measure for the cure of a disease, or as a procedure for the prolongation of life, the prevention of impending death, or the amelioration of a patient's condition. The operation is performed in recto-vesical fistula which cannot be closed by a local operation, in certain varieties of non-malignant ulcerations of the rectum, and in congenital malformations in which the anus and rectum are absent. It is also often performed as a preliminary procedure previous to excision of the rectum by the sacral method. As a proceeding for the prolongation of life, it is most commonly performed on patients suffering from cancer of the rectum when the growth cannot be locally removed.

Position.—The patient is placed in the dorsal position near the left side of the operating table. The surgeon stands on the left side of the patient, and the chief assistant opposite to him.

Operation.—Inguinal colotomy may be divided into three stages, namely—

(a) *Parietal incision.*—An incision from 2 to 3 in. in length, according to the obesity of the patient and the thickness of the abdominal walls, is made in the following manner:—An imaginary line is taken from the left anterior superior iliac spine to the umbilicus, and a point is selected along this line one-third of the distance from the iliac spine. The incision is made to pass through this point at right angles to the imaginary line, one-half of this incision being above, and the other half below, the

FIG. 98.—Inguinal colotomy.
Position of parietal incision.

line (Fig. 98). This incision is made to divide all the strata of the abdominal wall until the peritoneal cavity is opened.

(b) *Finding of the bowel and fixation to the abdominal wall.*—

FIG. 99.—Inguinal colotomy. Diagrammatic section through the sigmoid flexure, showing line of insertion of sutures.

a. Mesentery. *b.* Abdominal wall. *c.* Colon.

The colon may at once protrude in the wound, but if not, the fingers are passed into the peritoneal cavity and the large intestine sought for. It will usually be found a little below and external to the incision. In abnormal conditions it may be found over the brim of the pelvis and towards the right side. The large intestine can be recognised by its sacculations, the presence of appendicæ epiploicæ upon its surface, and the arrangement of its longitudinal muscular coat in the form of three distinct bands, one of which is directly opposite the mesenteric attachment. In order to prevent prolapse, the sigmoid flexure is drawn down from above until the upper segment is quite taut, the coils being passed in again below. A loop of intestine is then selected as near the descending colon as possible, and into the convexity two guiding sutures are passed, $1\frac{1}{2}$ in. apart, and through the serous and muscular coats. These sutures are left as loops, one knot being placed on the upper and two on the lower, in order to enable the surgeon to recognise the exact position of the intestine when it is opened in the third stage of the operation. The loop of intestine is returned into the peritoneal cavity, and the parietal peritoneum fixed to the skin on each side of the incision by the insertion of two silk sutures on each side. The loop of intestine is again brought out into the wound, and fixed to the margins of the incision by seven or eight sutures on each side, the terminal suture at each extremity going from one side to

The colon may at once protrude in the wound, but if not, the fingers are passed into the peritoneal cavity and the large intestine sought for. It will usually be found a little below and external to the incision. In abnormal conditions it may be found over the brim of the pelvis and towards the right side. The large intestine can be recognised by its sacculations, the presence of appendicæ epiploicæ upon its surface, and the arrange-

FIG. 100.—Inguinal colotomy. Operation completed, but the gut has not yet been opened.

the other, and picking up the intestine half an inch beyond the guiding sutures. The sutures are so inserted that two-thirds of the circumference of the bowel are distal to the lines of insertion and one-third between them. Each suture is made to pass through the skin, fasciæ, and peritoneum of the abdominal wall, and through the serous, muscular, and submucous coats of the intestine, care being taken not to perforate the mucous membrane. The sutures on the inferior and left side of the bowel are passed through the posterior longitudinal band, and the upper ones just beyond the mesenteric attachment (Fig. 99). Thus a "spur" is formed by the intervening portion of gut, whose object is to direct the passage of the contents of the descending colon into the artificial anus.

After all the sutures have been introduced, they are tied and the ends cut short. If the parietal wound has been made larger than the protruded loop of intestine, the portions to which the intestine is not attached are closed in the usual manner.

(c) *Opening of the gut and making an artificial anus.*—The intestine may be opened at the time of the operation: when opened at a subsequent date the administration of an anæsthetic is not necessary. If the symptoms are not urgent, it is advisable to leave it for three to five days, an aseptic dressing being applied in the meantime. In opening the bowel the two guiding sutures are taken, one is given to an assistant to hold, and an opening is made into the interior of the gut by cutting between these sutures with a scalpel. The superfluous portions of the gut around the artificial anus are trimmed away with scissors, and all bleeding points ligatured. The hæmorrhage may be considerable.

Prolapse of the mucous membrane of the portion of the intestine immediately above the external aperture very rarely follows this variety of operation. In order to control the escape of fæces, it is advisable to fit up the patient with a truss similar to the one figured in Fig. 101.

Inguinal colotomy without sutures (Maydl and Reclus'

FIG. 101.—Inguinal colotomy. Truss for use after this operation.

operation).—The early stages of this operation are exactly similar to those of the operation above described. When the loop of sigmoid flexure has been brought into the parietal wound, and made taut above, a small aperture is made in the mesentery immediately behind the bowel and in the middle part of the loop, and through this a glass rod, about 4 or 5 in. in length, is passed, and fixed to the abdominal wall by two pieces of strapping. The rod is so placed that the loop of intestine lies above it, and it is fixed in a position at right angles to the long axis of the external wound. Dressings are applied in the usual manner, and at the end of a few days, according to the urgency of the

case, the bowel is opened in a manner similar to that described above. The glass rod should be left in position for a week, and then removed.

The advantages which are claimed for this operation are the short time necessary for its performance, and the excellent results which have followed its adoption. In my opinion, however, the "suture" method is the best.

Inguinal colotomy with immediate opening of the gut.—In some cases it is desirable to afford instant relief to the contents of the colon, whilst the patient's condition will only warrant the smallest operation possible. For these it is convenient to adopt the appliance known as "Paul's tube," which consists of a glass tube about $\frac{3}{4}$ in. in diameter and 5 in. long, bent at right angles near the centre with a double flange at each end.

FIG. 102.—Glass tube for use when the colon is opened at once.—PAUL.

The gut having been found and fixed to the abdominal wall, as described above, a small incision is made in it, surrounded with a "purse-string" suture, the tube inserted, and the suture drawn tight between the flanges; a continuation of rubber tubing is attached to the distal end of the tube, and the wound partially closed and dressed.

The end of the rubber tubing is maintained in connection with a suitable vessel under the side of the bed.

Lumbar colotomy.—The term lumbar colotomy implies the creation of an artificial opening in either the ascending or descending colon, through an incision made in the right or left lumbar region.

Indications.—The indications for the performance of this operation are for the most part similar to those enumerated in connection with inguinal colotomy, and by a few surgeons it is preferred to the latter. The inguinal variety of colotomy is, however, generally preferred, on account of the fact that the artificial anus is in a position where it can be more easily managed by the patient, fewer difficulties are likely to be met with in the performance of the operation, and septic cellulitis is not so liable to be established in the region of the wound. The lumbar operation has the advantage that the opening in the intestine is placed further above the focus of the disease in cases of cancer of the rectum, the condition for which the operation of colotomy is most frequently performed. The anatomy of the parts concerned in the operation of lumbar colotomy is shown in Fig. 103.

Position.—The patient is placed in a semiprone position, lying on the sound side. A hard round pillow or a sandbag is placed under the loin, so as to separate as far as possible the crest of the ilium from the lower margin of the last rib. The surgeon stands behind the patient opposite the loin, and the chief assistant opposite to him.

FIG. 103.—Diagrammatic representation of a transverse section through the trunk at the level of the upper portion of the third lumbar vertebra, showing relations of anatomical structures concerned in lumbar colotomy.

| c. Transversalis abdominis. | h. Ureter. |
| d. Colon. | i. Abdominal aorta. |
| e. Quadratus lumborum. | j. Inferior vena cava. |

Operation.—The line of the colon is marked out on the surface of the body, by drawing a line vertically upwards from a point half an inch behind the centre of the crest of the ilium to the lower border of the last rib.

The operation may conveniently be divided into three stages, namely—
 (a) *Parietal incision.*—The central point of the line which marks out the colon between the iliac crest and the last rib is taken, and an incision from $2\frac{1}{2}$ to 3 in. in length is made, which is parallel to the lower border of the last rib and passes through this point. A little more of the incision is made posterior to the vertical line than anterior (Fig. 104). The

incision commences in front, and passes upwards and backwards. The skin and fasciæ are first divided, and then in succession the posterior fibres of the external oblique and the anterior fibres of the latissimus dorsi. The posterior fibres of the internal oblique and transversalis, the lumbar fascia and external portion of the quadratus lumborum, and, lastly, the fascia transversalis. The loose connective tissue, containing a quantity of fat in its meshes, which covers that portion of the colon devoid of peritoneum, is now exposed. This is carefully broken down or teased away with the fingers or dissecting forceps, so as to expose the posterior aspect of the colon.

(b) *Finding of the colon, bringing it into the external wound, and fixation of it.*—When the connective tissue surrounding the colon is being teased away, care must be taken not to make a hole into the peritoneum. The colon can best be recognised by feeling for it, the tissues in the bottom of the wound being grasped between two fingers. The colon is more resistant, and feels thicker than either the peritoneum or a coil of small intestine. It is not often possible to distinguish the longitudinal arrangement of the fibres of its muscular coat. In many cases the colon at once

FIG. 104.—Lumbar colotomy. Position of patient and line of incision in lumbar colotomy. The dotted lines represent the lower border of the last rib, the iliac crest, and the outer border of the erector spinae muscles.

bulges into the external wound when the fascia transversalis has been incised. If difficulty is met with in finding the colon, its discovery may be facilitated by the assistant exerting pressure from the front so as to lift the gut backwards, or by inflating the intestine with air through the anus. It occasionally happens that the colon has a complete mesentery (on the left more commonly than on the right), or it may have an abnormal position within the abdomen. In these cases it will be impossible

to find the gut without opening the peritoneal cavity; and if this becomes necessary, it is better to close the lumbar incision and perform an inguinal colotomy, unless the colon can be readily felt at the bottom of the lumbar incision and connected to the posterior abdominal wall by a mesentery, in which case the operation will be completed either by stripping off the peritoneum from the colon, or by opening the peritoneal cavity and bringing out the gut through the aperture thus made. When the intestine has been exposed and brought into the wound, an area about three-quarters of an inch square is laid bare, through which the fistulous aperture can be made. If it is desired to open the bowel at once, two moderately strong silk sutures are taken and threaded with a needle at each end. One suture is passed into the cavity of the intestine at one angle of the exposed area, and out again at the other angle of the same side, and the second ligature is passed in a similar manner at the other side. These ligatures are given to an assistant to hold, whilst the surgeon makes an incision into the bowel at right angles to its long axis, and in the middle of the area included within the ligatures. A blunt hook is passed into the interior of the gut, and the loops of ligature are brought out. These are cut in the middle, and then the margins of the opening can be held apart by

two ligatures on each side. The free end of each ligature, to which a needle is attached, is made to pass through the tissues bounding the external incision, and come out through the skin. Next, a suture is passed from one side of the incision to the other, a short distance beyond the sutures already introduced, and taking up the intestine just beyond the angle of the opening in it, but not passing into the interior of the gut, the muscular and submucous coats alone being seized. The sutures having been introduced in this manner, all are tied and the ends cut short. The margins of the incision in the bowel are lifted well over the margin of skin of the parietal wound as the ligatures are being tied. If any part of the external wound remains open, it is closed in the usual manner. When there is no urgency as regards opening the bowel, the exposed area is fixed in the external wound by passing two long hare-lip pins through the muscular coat. The other parts of the wound are approximated by the insertion of silk sutures. Dressings are applied, and the final stage performed several days later.

(c) *Opening of the gut.*—The intestine is opened by making an incision with a scalpel through that portion of tissue which lies between the hare-lip pins. After the incision has been made, it is sometimes possible to remove large masses of feces from the adjacent parts of the colon, a proceeding which often gives great relief to the patient. No anæsthetic is necessary for the opening of the intestine. It is advisable to fit up the patient with a bandage or truss which will be of use in controlling the evacuation of feces.

OPERATIONS UPON THE RECTUM AND ANUS.

Hæmorrhoids.—Hæmorrhoids or piles frequently require surgical treatment. The varieties of operation which may be adopted are the following, namely—(a) Treatment by ligature, (b) treatment by excision, (c) treatment by crushing. The method of treatment by ligature appears to be the most satisfactory, and moreover it is the easiest to carry out. The three operations will be described in order.

(a) *By ligature.*

Special instruments.—Clover's crutch, scissors, volsellum or pile forceps, and large size drainage tube.

Position.—The patient is placed in the lithotomy position, Clover's crutch being used, and the buttocks made to project slightly over the end of the operation table. The surgeon sits opposite the perineum, and the assistant stands on his right hand.

For some of the slighter operations, the right lateral and semiprone position may be found convenient, the surgeon standing behind the patient.

Operation.—As a preliminary to most operations upon the lower part of the rectum which are carried out from its interior, it is necessary to dilate the anus and cause temporary paralysis of the sphincters. This is done by introducing the index

fingers or thumbs of both hands through the anal aperture, and exerting continuous and firm traction, until the sphincter is felt to relax or give way. When this occurs, the pressure from within is diminished so as to avoid laceration and tearing of the muscle. In order to thoroughly dilate the anus in this manner, it is usually necessary to exert traction for three or four minutes. When the anus has been sufficiently dilated, the hæmorrhoids prolapse and become evident.

Application of the ligature.—The most prominent pile at the posterior margin of the anus is seized with the volsellum forceps and drawn inwards towards the middle point of the enlarged anal aperture. This renders apparent the junction of the skin and the mucous membrane. The scissors are taken, and a cut

FIG. 105.—Clover's crutch, for maintaining a patient in lithotomy position.

is made at the base of the pile and along the muco-cutaneous junction; and the hæmorrhoidal mucous membrane, with the attached pile, dissected upwards for a short distance until a distinct pedicle to the pile has been made. It is only necessary as a rule to make a few snips with the scissors in order to effect this. A strong silk ligature is then placed in the groove between the pile and the skin, the forceps and attached pile are pulled slightly outwards and downwards, and the ligature is tied in such a manner that all the blood vessels going to the pile are obstructed, and the knot is so placed that it lies upon the mucous membrane of the rectum. Transfixion of the base of the pile and ligature by a "Staffordshire" knot is another method by which this object may be effected. Any other piles which may be present are treated in a similar manner, but it

is not necessary even in severe cases to apply more than four ligatures. When all the ligatures have been tied, the distal portions of the piles are cut away, care being taken to leave a distinct button of tissue which shall prevent the ligature slipping. The ligatures are cut short, the area of operation washed with an aseptic solution, and an aseptic dressing applied and held in position by a perineal bandage.

Care must be taken in this operation not to include any of the skin of the anal margin, otherwise much pain may be induced, or it is possible that a stricture of the anus may afterwards develop.

(b) *By excision (Whitehead's operation).*

Instruments.—These are similar to the instruments required for ligature, with the addition of dissecting forceps and suture needle with needle-holder.

Position, as for ligature.

Operation.—The mucous membrane of the rectum is divided with scissors, at its junction with the skin, for the entire circumference of the anus, any irregularities of the skin being followed. By dissection, the hæmorrhoidal portion of the mucous membrane is separated from the submucous tissue which lies between it and the adjacent tissues, and then the ring of piles and mucous membrane is pulled down below the level of the anus. The mucous membrane is now divided just above the “hæmorrhoidal area,” and the diseased portion removed. The cut edge of the mucous membrane is united to the free margin of the skin by the insertion of a number of sutures. This is best done in stages; as a portion of the mucous membrane is divided, it is stitched to the free margin of the skin.

All the ligatures are cut short and a dressing applied, as in the previous operation.

(c) *By crushing.*

Instruments.—The instruments for this operation are the same as for ligature, with the addition of the special form of “pile-crushing clamp” preferred by the operator.

Position.—The position of the patient and operator are the same as for ligature.

Operation.—The anal sphincter is dilated in the usual manner, so as to allow of free access to the piles. The most prominent pile is selected, and the aperture in the clamp placed over it. A pair of volsellum forceps is passed through this aperture, and the pile seized and drawn through the opening. Whilst it is held in this position, the clamp is quickly screwed up tightly and the contained pile crushed. The clamp is left on for two

or three minutes, and the projecting portion of the pile removed with scissors or a cautery. The clamp is then unscrewed and removed, and if any bleeding points appear, they are picked up with pressure forceps and tied. Any other piles which may be present are treated in a similar manner. When this has been done, the region of the anus is freed from blood clot, and a dressing applied.

This operation does not appear to present any advantages over the "ligature"; it takes much longer to perform, and is moreover more likely to be followed by hæmorrhage.

Operation for "fistula in ano" (rectal fistula). — *Special Instruments.*—Clover's crutch, probe-pointed director, and sharp-pointed curved bistoury.

Position.—The patient is placed in the lithotomy position. Clover's crutch having been applied, with the buttocks projecting just beyond the end of the operation table. The operator sits opposite the perineum, and the assistant stands on his right hand.

Operation.—If the fistula has an external opening, a probe-pointed director is pushed through it, made to pass along the track of the fistula and emerge in the cavity of the rectum through the internal aperture, if one is present; or if not, the point is forced through the thinnest portion of the mucous membrane which intervenes between the fistulous track and the lumen of the bowel. When the internal opening is only a short distance above the anal margin, the point of the director is brought out through the anus. If this can be done, a sharp-pointed bistoury is passed along the groove in the director, and all the tissues between the fistulous track and the surface divided. When the internal aperture is situated so high within the bowel that this cannot be done, the fore-finger of the left hand is passed into the rectum to the point of the director as it protrudes through the internal opening, and with a pair of scissors the intervening tissues between the track of the fistula and the lumen of the intestine are divided. Some surgeons in these cases pass a rounded piece of soft wood into the rectum as far as the internal opening of the fistula, and then a sharp-pointed bistoury is pushed along the fistulous track, until the point pierces the piece of wood within the rectum. The bistoury and the piece of wood are next withdrawn together, and the tissues divided. When the chief fistulous track has been opened by one of these methods, an examination of its upper extremity should be made, to ascertain whether there is a sinus extending further upwards, and if so, as is usually the case, it is opened

up with scissors on a director, unless it extends so far that there is danger of hæmorrhage occurring where it cannot readily be controlled. Next, the lateral prolongations of the fistula are opened up. Care must be taken not to divide the external sphincter in more than one place, otherwise incontinence of fæces may follow the operation. The necessity for division in more than one place can be avoided in most instances, by opening the superficial portion of the sinus until the director has a straight track into the lumen of the bowel. In those rare cases in which there are two internal openings, it is better to open up the more extensive and larger fistula, and to scrape out the interior of the other one with a fine Volkmann's spoon, since in most cases this second track will then close, while the one which is laid open is granulating up. When the fistulous aperture is situated in the central part of the female perineum, the sphincter should not be divided at this point, since incontinence generally follows, owing to the interlacement of the fibres of the external sphincter ani and the sphincter vaginæ at this point. The best method of treatment in these cases is to treat the fistulous track by scraping, and then to divide the external sphincter in the middle line behind. The fistula will generally heal after this has been done, since the contractions of the muscle do not force fecal matter into the sinus, and the walls are allowed to remain at rest. When the fistula has been opened up by one of these methods, any projecting portions of unhealthy skin or granulation are removed with the scissors, and all bleeding points seized with pressure forceps and ligatured. The area of the operation is washed so as to free it from blood clot, and a strip of moistened antiseptic gauze is placed in the bottom of the track, and an aseptic dressing is applied.

After-treatment.—The ultimate success of this operation depends upon the careful after-treatment. The wound should be kept as clean and aseptic as possible by daily irrigation, and after this has been done a strip of lint is placed (as above) between the cut surfaces, so as to ensure healing up from the bottom and prevention of bridging over, which may be the cause of the development of secondary fistulæ. If any union of the granulations of the two sides is noticed, it ought to be broken down with a probe.

Excision of the rectum (from perineum).—*Indications.*—Excision of a portion of the rectum by the perineal method is indicated in cases of carcinoma which involves the lower three inches of the bowel, and does not extend to the adjacent structures except to a limited extent. The finger ought to be passed

beyond the region of the growth, and be able to feel healthy mucous membrane above.

When there is extensive infiltration of the surrounding tissues, or there are signs of secondary growths in other parts, the operation is contra-indicated.

The anatomical relations of the rectum and its relations to

| e. Lumen of rectum. | |

the surrounding structures are shown in Fig. 107, which is a representation of a vertical section through the pelvis.

Special instruments.—Strong, curved, sharp-pointed bistoury, straight probe-pointed bistoury, blunt-pointed and curved scissors, volsellum forceps and catheters.

Position.—The patient is placed in the lithotomy position, with

the buttocks projecting slightly beyond the end of the operation table, and raised somewhat by a pad. The surgeon stands or sits opposite the perineum, and the assistants stand on his right hand.

Operation.—The operation may be divided into three stages. It may be advisable to perform left inguinal colotomy as a preliminary measure.

(a) *External incisions.*—The forefinger of the left hand is passed into the rectum, until the tip of the coccyx can be felt (beyond the growth, if possible). A sharp-pointed curved bistoury is taken, passed into the rectum along the curve of the finger, and made to transfix the posterior wall of the rectum and all the tissues which lie between it and the tip of the coccyx, until the point emerges through the skin at the apex of the coccyx. A cut is made towards the anus with the bistoury, so as to divide all the tissues between the tip of the coccyx and the median line of the posterior margin of the anus. It is important to keep in the middle line, so as to avoid unnecessary hæmorrhage. A semicircular cut is next made around each lateral margin of the anus, commencing at one side of the median posterior incision, and terminating at a point in front of the anal aperture. This cut should be made through the mucous membrane and not the skin, if the extent of the growth will allow of this being done, and should extend well into the ischio-rectal fossa on each side.

(b) *Separation of the lower portion of the rectum.*—With the fingers the posterior and lateral portion of the rectum are separated from the surrounding tissues, until the levator ani is reached. This structure is divided with scissors. The bowel is next separated from its connections in front. If the patient is a male, a No. 12 bougie or catheter is passed into the bladder, and held in position by the assistant. The anterior wall of the rectum is seized either with volsellum forceps or the fingers of the left hand, and drawn backwards. The connections between the anterior wall of the rectum and the structures in front of it are divided by careful dissection with the scissors or scalpel, or both, until the upper limits of the disease have been passed. The catheter or bougie can be readily felt, and any damage to the urethra easily avoided. If the patient is a woman, the finger of the assistant should be placed in the vagina, so as to facilitate the separation and avoid making an aperture through the posterior vaginal wall. The plane of separation is made through the vaginal submucous tissue. When the dissection has been carried beyond the limits of diseased tissue, the

affected portion of the bowel can be removed, the line of division being through healthy tissue above the growth.

(c) *Removal of the bowel along with diseased tissues.*—The lower portion of the rectum is seized with volsellum forceps, and drawn downwards. With a strong pair of scissors the rectal wall is cut through transversely at the upper limit of the wound. It must be remembered that the peritoneum extends to within $2\frac{1}{2}$ or 3 in. of the anus on the anterior aspect of the bowel; posteriorly it does not reach lower than about 5 in. from this point. As the division is effected, free hæmorrhage occurs, which is controlled by at once seizing, with pressure forceps, each blood vessel as it commences to bleed. The diseased portion of the rectum, together with the growth, having been removed, all bleeding points are ligatured with fine silk, and the ends of the ligatures cut short. When all hæmorrhage has been arrested, the field of operation is examined, so as to

FIG. 107.—Excision of rectum. Bougie for use after excision of rectum by perineal method.—HARRISON CRIPT'S.

make sure that no diseased tissue has been left behind. It is of no advantage to bring down the divided edge of the mucous membrane and stitch it to the margin of the lower portion of the wound, since it has been found that the sutures always cut out, and serve no practical purpose. A rubber tube is now passed into the cavity of the rectum, and allowed to project through the external aperture. The space around is packed with aseptic gauze and wool, and a perineal bandage applied. The tube allows the passage of blood and gas from the rectum, and so removes a source of discomfort to the patient.

After-treatment.—This has for its object the prevention of septic processes and the development of cicatricial contraction. The first complication is avoided by attention to cleanliness, and the avoidance of the accumulation of any discharge which may undergo decomposition. The occurrence of cicatricial contraction is prevented by the daily passage of a rectal bougie, during the process of healing of the wound. The passage of this instrument should be commenced immediately signs of contrac-

tion appear. Contraction usually commences within two to four weeks from the time of the operation. The bougie should be left in for three or four hours each day, if it does not cause discomfort. When the wound has healed, a process which takes about two months, the bougie is passed every other day, for about a year. The instrument is simply passed in and out, and not left for any length of time within the rectum.

Excision of the rectum by the sacral method (Kraske's operation).—Removal of a portion of the rectum by this method is indicated in those forms of carcinomatous growths of the viscus which are situated at a level at once too high up for removal by the perineal method, and too low down to allow of removal through an abdominal incision; that is to say, when the growth is located at or near the junction of the upper and middle thirds of the rectum.

In some cases unapproachable by the perineal route, and yet not sufficiently extensive as warrant the sacral method, the diseased tissues may be removed after *excision of the coccyx alone*, as in the preliminary steps of Kraske's operation.

Special instruments.—These are similar to those required for the "perineal" operations, with the addition of a small saw, a chisel, a mallet, a spatula, and bone forceps.

Position.—The patient is placed in the right lateral and semiprone position. The surgeon stands behind the patient, opposite the sacrum, and the assistant on his left hand.

Operation.—The operation of excision of the rectum by the sacral method may be divided into the following stages, namely—

(a) *External incision.*—An incision is made in the middle line, commencing above at the spine of the second sacral vertebra, and extending downwards to within an inch or so of the posterior margin of the anus, stopping short of the external sphincter ani. The soft structures are reflected as far as the lateral margins of the sacrum and coccyx on either side, and all bleeding vessels secured. The sacro-sciatic ligaments are left intact.

FIG. 108.—Excision of rectum. Position of incision in sacral operation.

(b) *Excision of coccyx, division of sacrum, and exposure of affected portion of rectum.*—The coccyx is resected, care being taken not to injure the underlying gut. This procedure is best carried out by introducing the index finger of the left hand into the rectum, and so following, by the sense of touch, each successive stroke of the knife. The bleeding is not excessive, though one or two vessels may require ligation.

The sacrum is now divided transversely, by means of an Adams' saw, at the level of the third sacral spine, the connective tissue attachments of the rectum to the anterior aspect of the bone having been previously torn asunder. This transverse cut through the bone must be done gradually and carefully, so as to avoid, if possible, any splintering. The detached portion is firmly held aside by the assistant, and a spatula having been placed along the anterior aspect of the bone, to protect the underlying structures, a longitudinal cut is made through the bone a little to the left of the middle line, so as to avoid entering the neural canal. This avoidance of the neural canal is necessary, not for the preservation of the contained nerves, as these have already been divided in the transverse cut, but in order to facilitate subsequent wiring of the fragments, since, if the vertical cut extends into the canal, it is more difficult to fix the bony fragments together. The lateral segments of the sacrum are now held aside, the attachments of their respective sacro-sciatic ligaments serving as hinges.

A good view of the rectum having been thus obtained, the exact extent of the growth must be made out, since the precise character of the subsequent steps in the operation depends upon this. As an examination through the anus may not allow the finger to pass high enough up, it is always advisable to make an opening through the rectal wall posteriorly, immediately below the lowest limit of the growth, taking care not to carry it further downwards than is necessary for the introduction of the finger. Having made out the exact limits, the next stage of the operation can be decided upon. This is usually the separation of that portion of the bowel which is involved in the growth from the surrounding structures.

(c) *Separation and removal of growth and adjacent portion of bowel.*—The gut is freed from its attachments all round, care being taken in the performance of this to avoid unnecessary laceration and damage to the tissues. In those cases in which the growth extends anteriorly, there may be considerable adhesion to the capsule of the prostate. If such exists, the prostatic capsule may be stripped off the gland, with little risk

of bleeding or other injury. The portion of the gut containing the growth is now excised, care being taken to make the sections well above and below the diseased segment. The division of the bowel is most conveniently made with strong scissors. This having been done, a search is made for any enlarged lymphatic glands in the vicinity, two or three usually being found lying in the hollow of the sacrum, on a level with the first sacral vertebra, in which case they must be removed. Should it be necessary to open the peritoneal cavity in the removal of the diseased bowel, the aperture must be closed by the insertion of a series of sutures.

(d) *Union of proximal and distal portions of rectum.*—If the growth is fairly limited, and the upper portion of the gut can be sufficiently drawn down to allow of circular “rectorrhaphy,” this can be proceeded with, after the manner which has been already described in connection with circular “enterorrhaphy” of the small intestine. When this can be done, it is not advisable to make the anastomosis complete, but rather to leave a gap posteriorly, to allow of the escape of fæces during the process of repair. If the anastomosis is completed, the bond of union will not, in most instances, be sufficiently firm to overcome the resistance of the external sphincter, and consequently there will be in all probability escape of fæces through the line of sutures, resulting in perirectal inflammation and abscess. When a gap is left, fæces can readily escape, and in time the fistulous track will be closed by cicatricial contraction. Should this, however, not take place, a plastic operation may be performed for its closure.

When the suturing has been completed, the bone flaps are placed in apposition, and united by the insertion of stout silk or wire sutures.

When the disease is too extensive to allow of approximation of the two ends of the gut, the upper end must be drawn out of the wound and sutured to the margins of the upper portion of the skin incision. In this case the bone flaps cannot be replaced, and must be removed, a circumstance which at once does away with one great advantage of the operation, namely, preservation of the natural support of the floor of the pelvis.

Closure of external wound.—This consists in closing the skin incision by the insertion of interrupted silk-worm gut sutures as far as is practicable. When circular “rectorrhaphy” has been performed, the skin incision must not be closed opposite the gap left in the posterior aspect of the rectal wall. The wound is then dressed with antiseptic dressings in the usual

manner; strips of strapping will be useful for keeping them in position.

Operation for imperforate rectum and anus.—The object of this operation is to establish a communication between the rectum and the perineal surface in those cases in which this is congenitally absent.

Indications.—The indication is the inability of the infant to defæcate, owing to the presence of a congenital malformation or deficiency, or the existence, on examination, of this defect, with or without the presence of recto-vaginal or recto-vesical fistule.

Special instruments.—Small speculum, trocar and cannula.

Operation.—The patient is placed in the lithotomy position. If an anus be present, the speculum is introduced and the cavity examined. Should a membranous diaphragm be the only obstruction in the lumen of the rectum or at the anus, this is perforated with a trocar or a scalpel, and the condition thus relieved. Otherwise the anal aperture must be dilated or enlarged, and careful dissection in the middle line pursued till the bulging lower bowel is found, which is then opened with the trocar or scalpel.

In those cases where no anus or anal dimple indicates the position of the perineal termination of the bowel, a median incision 1 or 2 in. in length must be made, and the dissection conducted thence inwards till the bowel is found. When this has been done, the lower extremity is incised.

There is no object in attempting to unite the mucous membrane of the bowel and the anus. The after-treatment necessitates the continued passage of bougies till stenosis no longer threatens.

Cases in which the attempt to find the bowel and establish an opening proves ineffectual, must be relieved by a left inguinal colotomy.

OPERATION FOR RADICAL CURE OF INGUINAL HERNIA.

Numerous operations have been devised for the cure of an inguinal hernia. Some of them are very complicated, whilst others are correspondingly simple. The operations which will be given are the one devised by myself, Bassini's procedure, and those practised by Kocher and Macewen.

Indications.—(a) Some cases of irreducible inguinal hernia; (b) those cases of strangulated hernia which are operated upon for the relief of the strangulation, and in which it is safe to perform a prolonged operation; (c) cases of reducible hernia in children and young people, in order to obviate the wearing of a truss. A number of other indications might be given, but for a discussion of these the student is referred to a text-book of surgery.

Special instrument.—Strong curved needle on a handle.

Position.—The patient is placed in the dorsal posture; the surgeon stands on the affected side of the patient, and his assistant directly opposite to him.

Anatomical considerations.—The inguinal canal is a space

lying between the different strata of the anterior abdominal wall, which commences internally at the internal abdominal ring—an aperture in the fascia transversalis—and terminates at the external abdominal ring—an aperture in the external oblique muscle. It is bounded *anteriorly* by the external oblique for its entire extent, and by the lowest fibres of the internal oblique for the external inch; *posteriorly*, by the fascia transversalis for the entire extent; and behind this, the deep epigastric vessels externally; and then, in succession, the middle inguinal pouch, the obliterated hypogastric artery, and the outer part of the internal inguinal pouch. Internally, in front of the fascia transversalis, is the conjoined tendon of the internal oblique and transversalis. The *floor* of the canal is formed by the grooved upper surfaces of Poupart's and Gimbernat's ligaments. The *roof* is formed by the arching fibres of the internal oblique and transversalis. The contents of the canal in the male are the constituents of the spermatic cord, together with the coverings of this structure which are derived from the fascia transversalis and the internal oblique. These are known as the infundibuliform fascia and the cremaster muscle respectively. The inguinal branch of the ilio-inguinal nerve lies in the superficial part of the canal, and emerges through the external abdominal ring.

In the female the inguinal canal contains the round ligament of the uterus, and the process of peritoneum known as the canal of Nück, together with coverings similar to those of the spermatic cord.

The following operation I have practised in all cases which have come under my treatment during the past five years. It has been consistently followed by good results, and, according to my observation of the other varieties of radical cure as practised by other surgeons, it is less liable to be followed by a recurrence of the hernial condition.

Operation.—The operation may be divided for convenience of description into the following five stages:—

(a) *Skin incision and exposure of external oblique and external abdominal ring with a portion of the hernial sac.*—An incision is made from $2\frac{1}{2}$ to 3 in. long, which commences half an inch internal to the pubic spine and over the middle point of the pubic crest, and extends upwards and outwards parallel with but a little above the line of Poupart's ligament (Fig. 109). This incision is made to divide the skin, superficial and deep fascia, with their contained superficial external pudic and superficial epigastric vessels, and to expose the external surface of the external oblique muscle, which is readily recognised by the whiteness of

its tendinous fibres and the semicircular arrangement of the intercolumnar fibres. When this has been done, the skin and subcutaneous tissues are dissected upwards from the surface of the external oblique muscle for about three-quarters of an inch, so as to fully expose the muscle and also the aperture of the external abdominal ring, and that portion of the hernial sac which protrudes through it.

(b) *Incision of external oblique, opening of inguinal canal, exposure of hernial sac and its contents.*—The external oblique aponeurosis is divided for the length of the first incision, but about half an inch higher. The incision commences at the attachment of the internal pillar of the external abdominal ring, and extends upwards and outwards parallel with the direction of the fibres of the muscle. The lower incised margin of the external oblique is then pulled downwards with a retractor, so as to expose the entire inguinal canal together with its contents. These are, in the male, the spermatic cord with some of its coverings, the hernial sac and its contents; in the female, the round ligament of the uterus, the hernial sac and its contents. The hernial sac is carefully opened with the scalpel, the wall of the sac being picked up with dissecting forceps, and its visceral contents (omentum, intestine, etc.) returned into the abdominal

FIG. 109.—Radical cure of inguinal hernia. a. External incision.

cavity. In cases of irreducible hernia, the cause of the irreducibility—such as adhesions, the presence of a large quantity of herniated omentum—must be dealt with before attempting to reduce the herniated viscus. Thus, adhesions must be tied in two places and cut between, whilst in the case of large pieces of omentum it is best to transfix them with a strong ligature and cut away the distal portion. It only occasionally happens that, in non-strangulated herniæ, it is requisite to divide the neck of the sac in order to return the herniated structures.

(c) *Treatment of hernial sac.*—The hernial sac is now separated by careful dissection from the constituents of the spermatic cord, especial care being taken not to cut or divide the vas deferens, a structure which can readily be recognised by its hard cord-like feel. This separation must extend downwards from the margins

of the internal abdominal ring, at the outer extremity of the incision, to the bottom of the sac. When the hernia is of the

congenital variety, it will be found to be continuous below with the tunica vaginalis testis. In this latter case the sac is transfixed a little above the testis and tied with a silk ligature. Next, a clamp is placed a little above the point of transfixion, and the sac cut through with scissors, on the distal side of the clamp and on the proximal side of transfixion. The hernial sac can now be lifted up, when it is seen to be quite free up to the internal abdominal ring. It is twisted upon itself, traction exerted upon it, and then transfixed with a hernia needle armed with a strong ^{double} ligature. This ligature is then tied—the two

- e. External oblique—lower portion.

halves separately—and the distal portion of the sac removed (Fig. 110). A hernia needle is now passed through the fibres of the internal oblique and transversalis abdominis muscle in the outer angle of the incision, and one end of the ligature which has fastened the sac passed through the eye of the needle. The needle is then withdrawn, and the two ends of the sac ligature tied and cut short. By this procedure, the parietal peritoneum, at what was the neck of the sac, is pulled downwards and firmly anchored to the abdominal wall. When this has been properly done, the site of the former internal abdominal ring and neck of the hernial sac is represented by a little prominence of peritoneum anchored to the abdominal wall. There is thus no

depression which might favour a recurrence of the hernial protrusion.

(*d*) *Obliteration of inguinal canal.*—The constituents of the spermatic cord are lifted up by an assistant with a retractor, and with a curved hernia needle a series of sutures is passed through the lower margin of the conjoined tendon of the internal oblique and transversalis, and the upper aspect of Poupart's and Gimbernat's ligaments; usually four or five are sufficient. After all these have been introduced, they are tied and their ends cut short. The spermatic cord is then placed on the superficial aspect of the conjoined tendon, in what may be called a new inguinal canal (Fig. 111).

FIG. 113.—Radical cure of inguinal hernia. Diagrammatic section through abdominal wall in region of inguinal canal, showing relative position of different tiers of sutures.

a, Skin and subcutaneous tissue; *b*, external oblique; *c*, conjoined tendon of internal oblique and transversalis muscles; *d*, fascia transversalis; *e*, peritoneum and extra-peritoneal tissue; *f*, pubis; *g*, suture fixing lower margin of conjoined tendon to upper aspect of Poupart's ligament; *h*, suture fixing together margins of incision in external oblique; *j*, suture fixing together margins of incision in skin and subcutaneous tissues.

(*e*) *Suture of external oblique and skin.*—The margins of the incision in the external oblique are approximated and fixed together by the insertion of a row of fine silk sutures (Fig. 112.). The wound is then sponged dry, and the margins of the parietal incision fixed together by a row of salmon-gut sutures.

Especial care should be taken to apply ligatures to the cut ends of the superficial epigastric and superficial external pudic arteries. If this is not done, a hæmatoma in the superficial part of the wound is likely to result, which can only be cured by opening up the wound, finding the bleeding vessels and ligaturing them.

One advantage of this form of operation is that the different tiers of sutures are not opposite one another, and consequently the repaired abdominal wall

is stronger. The exact position of the sutures is shown in Fig. 113.

Bassini's operation (radical cure of inguinal hernia).—The operation may be divided into the following five stages, namely—

(*a*) *External incision.*—An incision from 3 to 4 in. in length

is made parallel with and about half an inch above Poupart's ligament, commencing nearly an inch internal to the anterior superior iliac spine, and terminating over the middle of the external abdominal ring (Fig. 114). The skin and fasciæ are divided; one or two small arteries, the superficial epigastric and the ascending branches of the superficial circumflex iliac, superficial external pudic, requiring ligature. The aponeurosis of the external oblique muscle is next divided for the entire length of the incision.

(b) *Opening of inguinal canal, definition of sac of hernia and spermatic cord, and separation of these two structures.*

—The aponeurosis of the external oblique is dissected upwards and inwards as far as the outer border of the rectus abdominis, and downwards to the grooved

upper aspect of Poupart's ligament. Next, those portions of the internal oblique and transversalis which cross the bottom of the incision are divided a short distance above their attachments to Poupart's ligament. The internal abdominal ring will now be exposed in the outer part of the incision, and extending from this downwards along the inguinal canal will be seen the hernial sac and the constituents of the spermatic cord, which are often spread out over the sac of the hernia. By careful dissection the hernial sac is separated from the structures composing the spermatic cord, the latter being lifted up from the sac by blunt hooks.

FIG. 115.—Inguinal hernia ; radical cure. Entire inguinal canal open, spermatic cord lifted up, and first tier of sutures inserted but not tied. —BASSINI.

FIG. 114.—Inguinal hernia ; radical cure. Line of external incision. —BASSINI.

(c) *Removal of hernial sac, and union of internal oblique and transversalis muscles to Poupart's ligament.*—The distal part of the sac is laid open, and if any portion of the omentum, intes-

tine, or other viscus is inside, this is returned into the abdominal cavity, any adhesions which may be present being ligatured and divided. The sac is now held up, and the region of the neck where it lies within the internal abdominal ring separated from the surrounding tissues, and transfixed at the base with a blunt hernia needle which carries the loop of a silk ligature. This ligature is cut into two, and the needle withdrawn; each half of the ligature is tied around one-half of the sac and one around

the entire stump. The distal part of the sac is removed with scissors and the stump pushed inwards towards the abdomen. When the hernia is of the congenital variety, and the sac is continuous with the tunica vaginalis testis, it is necessary to cut across the sac, first a short distance above the testis, and then to proceed as above.

The cut margins of the transversalis and internal oblique muscles are now fixed to the upper margin of Poupart's ligament by the insertion of a row of interrupted silk sutures, according to the method shown in Fig. 115. During this procedure the spermatic cord is held out of the way by an assistant.

(d) *Replacement of spermatic cord, and union of external oblique to Poupart's ligament.*—The spermatic

cord is placed on the external surface of the internal oblique just above the line of its attachment to Poupart's ligament, and hence it comes to lie in a new canal. The aponeurosis of the external oblique is placed over the spermatic cord, and the cut margins united to Poupart's ligament by interrupted silk sutures.

(e) *Closure of external wound.*—This is closed in the usual manner.

The advantages which this operation is said to possess are the

FIG. 116.—Inguinal hernia; radical cure. First tier of sutures (Fig. 115) tied, and the ends cut short. The spermatic cord is placed in its new canal, and the second tier of sutures is inserted so as to unite the margins of the incision in the external oblique muscle. They are ready to be tied.—BASSINI.

easy and complete access which is given to the herniated structures, and the non-liability to relapse afterwards. The latter advantage, however, has been very much exaggerated. The disadvantages are the long incision which is necessary, and the complicated nature of the operation.

Kocher's operation (radical cure of inguinal hernia).—Operation.—An incision about 3 in. in length is made half an inch above and parallel to the inner two-thirds of Poupart's ligament. The skin and

FIG. 117.—Operation for radical cure of inguinal hernia. First stage: External incision, exposure of external oblique muscle, and laying bare of neck of sac.—KOCHER.

b. Incision in external oblique.

FIG. 118.—Operation for radical cure of inguinal hernia. Second stage, showing a pair of dressing forceps passed along the inguinal canal and grasping the hernial sac, which has been separated from its surroundings.—KOCHER.

fasciæ are divided, and the superficial epigastric and external pudic vessels cut across and ligatured. Next, the coverings of the hernial sac just beyond the external abdominal ring—the intercolumnar fascia, the cremasteric muscle and fascia, and the infundibuliform fascia—are incised, so as to expose the superficial aspect of the hernial sac. This sac is separated by dissection from its surroundings, and its fundus, which occupies the scrotum, pulled upwards. The distal part of the sac is now free.

The upper margin of the wound is strongly retracted upwards, and an opening made in the aponeurosis of the external oblique immediately above and external to the internal abdominal ring, that is, above and

external to the mid-point of Poupart's ligament. This opening is usually about 1 in. in length, and is large enough to allow the fundus of the empty hernial sac to be brought through it (Fig. 117).

A pair of curved dressing forceps is taken, the blades passed through the opening in the external oblique, then through the lowest fibres of the internal oblique into the inguinal canal, and thence along this canal anterior to the spermatic cord, until the points emerge from the external abdominal ring at the inner part of the first incision (Fig. 118).

The fundus of the hernial sac is next seized with the dressing forceps

FIG. 119.—Operation for the radical cure of inguinal hernia. Third stage, showing the hernial sac drawn upwards through the aperture in the external oblique muscle. Two sutures are shown passing through the neck of the sac and the interior abdominal wall (muscular and fascial layers).—KOCHER.

and drawn along the inguinal canal until it emerges through the aperture in the external oblique, by exerting traction in an upward and outward direction (Fig. 119).

An opening is now made at the distal extremity of the sac, and its interior examined so as to make sure that no gut or omentum is within. When the hernial sac is large and extends into the scrotum, it should be opened at the external abdominal ring, and, after reduction of its contents, divided transversely. The part which lies within the canal is treated as above, whilst the distal portion is dissected out from the scrotum and removed. The sac is then pulled downwards and outwards,

in order to draw down as much as possible of the neck and the peritoneum in the region of the internal abdominal ring. It is then transfixed with a needle carrying a strong ligature, tied in two halves, and the portion distal to the ligature removed with scissors.

The stump of the sac is now reduced through the aperture in the external oblique, and anchored to the deep aspect of this muscle by sutures which pass through the muscular and fascial layers of the abdominal wall, and also transfix the stump of the sac (Fig. 119). A deep suture is passed through the margins of the internal abdominal ring immediately below the neck of the hernial sac. The remainder of the incision in the external oblique is then closed in the usual manner by the insertion of one or two points of simple suture.

"Canal sutures" are now introduced so as to partially obliterate and also strengthen the anterior

FIG. 121. — Radical cure of inguinal hernia. Folding of sac. The figure shows the sac transfixed with a ligature, and thrown into a number of folds. — MACEWEN.

FIG. 122.—Radical cure of inguinal hernia. Hernia needle. — MACEWEN.

wall of the inguinal canal, according to the method illustrated (Fig. 120).

The external incision is then closed by the insertion of a row of interrupted sutures of silk-worm gut, and aseptic dressings applied.

The advantage of this operation is that the muscles which form the anterior boundary of the inguinal canal are not cut through, and the canal is not opened up for its entire extent. The spermatic cord is not interfered with as in Bassini's operation.

Macewen's operation (radical cure of inguinal hernia).—In this

operation the hernial sac is thrown into a series of transverse folds, by means of a suture which passes through it several times. The sac is then reduced, and fixed in position opposite the internal abdominal ring, and the inguinal canal is closed by the insertion of a number of sutures.

Operation.—The positions of the patient, surgeon, and assistant are similar to those in the preceding operations.

External incision, exposure, and treatment of hernial sac.—An incision is made in the inguinal region, directly over the external abdominal ring. This is deepened until the external ring and the neck of the hernial sac have been well explored. The contents of the sac are then reduced into the peritoneal cavity, the fundus of the sac is separated

FIG. 123.—Radical cure of inguinal hernia. Manner of transfixing the sac. The hernia needle has passed through the sac in several places, and pierced the abdominal muscles from behind forwards, emerging about an inch external to and a little above the internal abdominal ring.
—MACEWEN.

from the scrotum, and the neck from the wall of the inguinal canal as far as the internal abdominal ring. This is done by the point of the forefinger, care being taken to separate it freely around the margins of the internal ring, and to define the position of the deep epigastric artery. The fundus of the sac is pulled out from the scrotum, and then the entire sac is folded upon itself, as in Fig. 121, and transfixed with a hernial needle of the shape shown in Fig. 122, the point of the needle emerging through the external oblique a little above and external to the position of the internal abdominal ring (Fig. 123).

The needle is withdrawn, and traction being exerted on the thread, the sac is drawn upwards along the inguinal canal, and fixed opposite the external aspect of the internal abdominal ring.

Closure of inguinal canal.—The conjoint tendon is pierced with the hernial needle, carrying a suture, in two places as in Fig. 124; and the needle withdrawn, leaving the suture in position.

FIG. 124.—Radical cure of inguinal hernia. Method of transfixion of conjoint tendon in two places, with hernial needle carrying a suture.—MACEWEN.

FIG. 125.—Radical cure of inguinal hernia. Suture ready for tying, after the conjoint tendon has been pierced in two places, and also Poupart's ligament.—MACEWEN.

Next, each extremity of this suture is carried separately through Poupart's ligament, as in Fig. 125.

A sufficient number of sutures are introduced in this manner; usually two, or at most three, are necessary. Each suture is then tied in a reef knot, and the ends cut short.

The external wound is then closed in the usual manner, and aseptic dressings applied.

The advantages which have been claimed for this method are the closure of the inguinal canal and the internal abdominal ring which is effected, and the good results which have followed the operation.

A disadvantage is the complicated nature of the procedure, and the difficulty which is experienced in carrying it out in young children.

OPERATION FOR RADICAL CURE OF FEMORAL HERNIA.

Several varieties of operation have been recommended for the radical cure of a femoral hernia.

FIG. 126.—Femoral hernia. Line of incision.

It is doubtful, however, if any of them can be regarded as certain in their results, since recurrence is quite common after their performance if the patient does not wear some form of truss or support. There is no doubt, however, that the performance of an operation, such as the one described later, facilitates the retention of a femoral hernia, and allows the patient to wear a lighter form of truss. The operation devised by Roux appears to be the best for curing the hernia.

Position.—The patient lies in a dorsal position, with the limb of the affected side slightly flexed, abducted, and rotated outwards, a pillow being placed under the knee. The surgeon stands on the affected side of the patient, and his assistant on the opposite one.

Special instrument.—Hernia needle.

Operation.—The operation may be divided into four stages, which are—

(a) *External incision and exposure of sac.*—An incision is made in the long axis of the hernial swelling, commencing in front of Poupart's ligament, and half an inch outside the pubic spine, and extending downwards for about 2 in. The skin, superficial fascia, cribriform fascia, and the fascia of the

femoral sheath, are divided, and the superficial aspect of the hernial sac exposed. This can be recognised by its tenseness, its slaty-blue colour, the arrangement of the blood vessels upon its surface—these are said to be arborescent—and by the fact that the sac itself can be picked up, and made to glide over the contents. The sac is carefully divided up to the femoral ring. The surgeon can often recognise that he has divided the sac wall by the escape of a quantity of clear fluid (blood-stained in the case of a strangulated hernia). The contents of the sac are next examined, and dealt with as is considered proper. If any adhesions are met with, they are separated either by breaking them down with the finger if they are recent, or by ligature if of old standing.

(b) *Treatment of sac.*—When the sac has been exposed and opened, and the contents returned into the abdominal cavity, its neck is well separated with the finger from the surrounding tissues above the femoral ring. Traction is exerted upon it, and a ligature applied around its neck as high as possible. If the sac is small, the ligature may simply surround the neck, but in most instances it is advisable to transfix the neck as high as possible, and to tie it in two halves, as in the case of inguinal hernia.

When these ligatures have been tied, the ends are kept long, and the sac removed beyond the line of application of the ligature, sufficient being left in the stump to ensure non-slipping of the ligature. The stump is now pushed upwards into the abdomen, and one end of the ligature, which has been left long, passed through Poupart's ligament and tied to the other extremity, and cut short. This helps to anchor the stump to the abdominal wall, and to keep it immediately above the aperture of the femoral ring.

(c) *Treatment of femoral ring and canal.*—The femoral ring can be closed by passing one or two ligatures through that portion of Poupart's ligament which lies in front of the ring, and then through the attachment of the pectineal fascia to the ilio-pectineal line (Fig. 127). Two ligatures of this kind are usually enough. Care must be taken not to perforate the

FIG. 127. — Femoral hernia. Method of fixation of neck of sac to Poupart's ligament.

- a. Stump of hernial sac.
- b. Common femoral vein.
- c. Sutures.

common femoral vein, which lies immediately outside the femoral ring. The femoral canal can be, in part, obliterated by dissecting up a flap of the pectineus muscle and its fascia,—the convexity of the flap being below, and the attached base above,—and fixing this to Poupart's ligament by the insertion of a few interrupted silk sutures.

(d) *Closure of external wound.*—The margins of the aperture in the deep fascia are united by a continuous suture, and the skin wound is closed in the usual manner.

Roux's operation.—Roux of Lausanne has devised the following operation for the radical cure of a femoral hernia, which appears to overcome many of the difficulties and objections to other operations. The operation is performed thus:—A vertical

incision is made over the hernial swelling as in the previous operation, the sac isolated and opened, and the contents, if any, returned within the abdominal cavity. Next, the neck of the sac immediately below the crural ring is surrounded by a thick cat-gut ligature, which is tied, and then the portion of the sac beyond the ligature cut away. A rectangular "staple," of the shape shown in Fig. 128, *a*, is then taken and passed through the inner portion of Poupart's ligament, in such a manner

FIG. 128.—Roux's operation for femoral hernia.

- a.* Metallic "staple."
- b.* Commencement of introduction.
- c.* Driven into bone.

that one limb of the "staple" is just internal to the crescentic border of Gimbernat's ligament, and the outer one immediately internal to the common femoral vein, until it comes into contact with the pubic ramus, when a hammer is taken and the "staple" gently driven into the bone until the crural ring is practically obliterated by the deep aspect of the crural arch coming into

contact with the pubic ramus. The "staple" must not be driven in too tightly, so as to constrict the tissues of Poupart's ligament; and especial care must be taken to avoid the common femoral vein, which lies immediately to the outer side of the outer limb of the "staple." When this has been done, the external wound is closed by sutures.

The presence of the metallic "staple" in the bone does not appear to give rise to irritation, and the hernia appears to be effectively cured. A truss ought not to be worn after this operation.

OPERATION FOR RADICAL CURE OF UMBILICAL HERNIA.

Many cases of umbilical hernia in adults, if other conditions allow, ought to be submitted to operation for the radical cure of the abnormal condition, since it is very difficult to keep up an umbilical hernia with a truss. Often, however, the patients are elderly females who suffer from bronchitis, and in these an operation, except in cases of emergency, is not desirable. The small umbilical herniæ of children can usually be cured by the application of a suitable pad.

Position.—The patient is placed in the dorsal posture, the surgeon stands on the right side of the patient, and the assistant directly opposite to him.

Operation.—The stages of the operation are—

(a) *External incision and exposure and opening of sac.*—An incision is made in the middle line of the abdomen over the tumour (if this is large, over its lower part), and deepened until the sac has been opened. Care must be taken when making this incision, since it often happens that the wall of the hernia is very thin, and the contents of the sac may be easily injured owing to the presence of adhesions. The safest method is to pick up a small portion of the sac wall with dissecting forceps, and then divide it. It is not always easy to demonstrate the wall of the sac before opening it, but this should be done if possible.

(b) *Treatment, and return of contents of sac.*—The sac having been opened for a distance of about 1 in. or more, the contents are examined, and the constriction, if any, made out. This may be due to adhesions of the contents to one another, or to the wall of the sac, or be caused by an additional loop of intestine having been suddenly forced into the sac. When the seat of constriction has been made out, it is divided, and a complete examination of the herniated structures made. If adhesions are present, they are separated; the contents of the hernial sac are

then returned into the abdominal cavity. If the sac contains a large piece of omentum, it is usually advisable to unravel it, transfix it in several places, tie it in segments, and then remove the distal portion. The contents of the sac having been dealt with, the aperture in the aponeurosis is temporarily plugged with a flat sponge, which will prevent the further escape of intestines.

The sac is now dissected from its connections with the surrounding tissues until the neck is reached. If possible, the peritoneum which forms the sac should be separated from the margins of the aperture in the aponeurosis, and then sewn up with a continuous silk suture, the sponge plug being first removed. The portion of the sac beyond the line of suture is removed with scissors, and the stump pushed inwards towards the abdominal cavity.

(c) *Closure of aperture in aponeurosis, and external incision.*—The margins of the aperture in the aponeurosis are pared away until the sheath of the rectus abdominis muscle on each side is opened. Next, the margins of the aperture are united together by the insertion of interrupted sutures. This may be done in one or more tiers. Usually the cut margins of the posterior layer of the sheath of the rectus are united to one another, then the margins of the two recti are approximated, and finally the anterior layers of the sheath.

The margins of the incision in the skin and fasciæ are united in the usual manner.

OPERATIONS FOR STRANGULATED HERNIA.

The most common herniæ are inguinal, femoral, and umbilical; obturator, sciatic, gluteal, and internal herniæ are rare. All varieties may become strangulated and require surgical intervention in order to save life. The operations for the relief of inguinal, femoral, umbilical, and obturator herniæ will be described.

Special instruments.—Needle on handle, hernia knife. In those cases in which resection of bowel is necessary, Murphy's "anastomosis button," or a "bone tube" or "bobbin," will also be required, if the surgeon wishes to use one of these mechanical appliances.

Care must be taken not to injure the contents of the hernial sac by rough treatment during the preliminary preparations of the skin over the field of operation.

Strangulated inguinal hernia.—*Position.*—The patient is

placed in the dorsal posture, with the thighs slightly flexed, so as to relax the tissues in the region of the external abdominal ring. The surgeon stands on the affected side, and his assistant opposite to him.

Operation.—The operation itself may be described as consisting of the following stages, namely—

(a) *External incision and exposure of the sac.*—An incision is made over the prominent portion of the hernial swelling, parallel to its long axis, and so situated that it extends a short distance above the external abdominal ring. This incision divides the skin and the fascial layers which cover the sac. It is not usually possible to recognise all the anatomical strata which form the coverings of a hernia, but often the intercolumnar fascia and the cremasteric layer can be distinguished. The wall of the sac can generally be recognised by its tenseness.

(b) *Opening of the sac, examination of its contents, and division of the stricture which causes strangulation; treatment of the herniated viscus, and return of it into the abdominal cavity.*—When all hæmorrhage from the superficial pudic arteries has been arrested, a small piece of the sac wall is picked up with forceps and carefully divided with the scalpel. An escape of fluid indicates the opening of the sac. This fluid is generally blood-stained serum, but it may be

FIG. 129. — Inguinal hernia. Line of external incision in a case of strangulation.

purulent or consist of intestinal contents, though the latter condition is very uncommon. Often, however, this fluid contains septic micro-organisms, hence it is advisable to irrigate the interior of the sac with an antiseptic solution before dividing the constriction. A director is passed through the aperture made in the wall of the sac, and the opening is enlarged until the contents of the hernia are fully exposed. An examination of the intestine, omentum, or other viscus, is now made, and its condition determined. If it is in a moderately healthy condition, such as will justify its return into the abdomen, the neck of the sac is freed and the situation of the stricture made out. The forefinger of the left hand, or a hernia director, is passed to the stricture, and when a director is used it is passed through it. The hernia knife is now passed along the finger or the director, and one or two small

notches made into the tissue forming the constriction, upwards and outwards, until the opening is made large enough to allow the return of the herniated structure. This having been done, the director or finger is withdrawn, and in the case of intestine the loop is pulled downwards so as to allow the surgeon to make a visual examination of the gut wall which has been nipped in

FIG. 130.—Hernia director.

the stricture. If this is found to be non-gangrenous, the contents are gradually and gently manipulated back into the abdominal cavity. In the case of omentum, it is generally advisable to remove the herniated portion, after transfixing its base with a ligature, and tying it. If this piece is large, it should be drawn downwards, unravelled, and then transfixed in several places, tied in sections, and the distal portion removed.

The vitality of the herniated loop of intestine can be determined in most instances by testing it for the presence or absence of peristaltic movements in its walls, and by minutely observing the state of the circulation in the blood vessels. If the intestinal wall be pinched either with the fingers or dissecting forceps, and a wave of peristaltic movement follow the procedure, it may be safely assumed that the loop is not in a condition of gangrene. After division of the constriction at the neck of the sac, the herniated loop should be drawn downwards into the wound, and the line of constriction carefully investigated for ulceration or perforation. The colour of the herniated loop and the state of the endothelial covering of the peritoneal coat must also be carefully noted, and if any doubt exists as to the vitality of the part, it should be washed with warm saline solution. If by this treatment the

colour of the bowel changes from a deep purple, or even black, to a reddish colour, then there is no doubt that the vitality of the herniated loop is such that it can at once be returned into the abdominal cavity. When no changes are visible in the state of the circulation, the surface of the gut should be pricked with the point of a scalpel or a needle. This will show whether the circulation has been completely arrested or not. When the peritoneal coat of the loop of the bowel has

lost its usual shiny appearance, and has rough greyish shreds upon it, this indicates that the loop has lost its vitality, is in a state of gangrene, and ought not to be returned. The condition of the mesenteric veins in the prolapsed tissues should also be examined, and if they are found to be thrombosed, it is strongly in favour of gangrene having been established, and hence in such cases the bowel ought not to be reduced.

When it has been determined that the loop of intestine within the hernial sac is in a condition of gangrene, the further treatment depends upon the general condition of the patient. When the patient is much collapsed, and not likely to survive a prolonged operation, the herniated loop of intestine should be anchored in the wound by the insertion of one or more sutures through its mesentery, and then the lumen opened so as to allow the contents to escape. If the constriction at the neck of the sac is so tight as not to allow the ready escape of intestinal contents, it should be notched sufficiently to permit a free outflow. Drainage is thus established, and dressings are applied. If the patient survive, resection of the remains of the gangrenous loop and end-to-end anastomosis are carried out at a later period, when the general condition has been much improved.

When the general condition of the patient is good, the gangrenous loop of intestine should be brought well into the wound, surrounded with warm sterilised towels, and the dead portion removed by performing intestinal resection, after the method described on pp. 79 *et seq.* It is advisable to allow the intestinal contents to escape before completing the anastomosis.

(c) *Closure of the hernial aperture, and suturing of the external wound.*—These stages of the operation are similar to those described in connection with the radical cure of an inguinal hernia (pp. 20 *et seq.*).

Strangulated femoral hernia.—*Position.*—The patient is

FIG. 131. — Operation for strangulated hernia. Hernia knife.

placed in the dorsal position, with the leg of the affected side slightly flexed. The surgeon stands on the affected side, and his assistant directly opposite to him.

Operation.—The stages of the operation are similar to those described in connection with inguinal hernia (*q.v.*).

An incision about 2 in. long is made in the long axis of the hernial swelling, and is so situated that the upper extremity is a little below and half an inch external to the pubic spine. This incision is in most cases on the inner aspect of the hernial swelling. The incision is deepened until the sac has been opened. In dividing the stricture the cut must be made upwards and inwards, so as to notch the free edge of Gimbernat's ligament, and to avoid the common femoral vein, which is on the outer side. In a small number of cases, 1 in 70, the obturator artery is given off from the deep epigastric, and runs in front of the neck of the sac. When this abnormality occurs, it may be divided, in which case the wound must be enlarged and a ligature applied to the cut extremity. The treatment of the hernial contents is similar to that mentioned in inguinal hernia, whilst the treatment of the sac and closure of the ring and wound are the same as in the radical cure of a femoral hernia (*q.v.*, p. 133).

Strangulated umbilical hernia.—When an umbilical hernia becomes strangulated, the sac must be opened by a vertical incision over it.

The contents are dealt with according to the methods described in the chapter on inguinal hernia, and this having been done a radical cure is performed, as described on p. 135. When the condition of the patient will not allow of resection of gangrenous bowel, the dead portion is opened and the loop fixed in the external wound, an artificial anus being established. If the patient recovers, this opening can be closed at a later period, and the hernial aperture closed as in the radical operation.

Strangulated obturator hernia.—In the treatment of a case of strangulated obturator hernia, an incision is made in the long axis of the swelling and on the inner side of the femoral vessels. This is deepened, the pectineus muscle and fasciæ being incised until the hernial sac is reached, which structure is opened in the usual manner. The stricture can be relieved by notching the obturator membrane at the inferior margin of the aperture. When the intestine is gangrenous, or when perforation has taken place, it is necessary to open the abdomen by an incision in the corresponding linea semilunaris, and to perform the requisite procedures from within the peritoneal cavity.

CHAPTER VI.

OPERATIONS UPON THE LIVER AND BILIARY SYSTEM.

THE following operations will be described, namely—

1. UPON THE LIVER.

Hepatotomy—Abdominal and transthoracic.

(1) for hydatid cysts.

(2) for abscess.

Hepatectomy.

Ruptures and wounds of the liver.

2. UPON THE BILIARY SYSTEM.

Cholecystotomy.

Cholecystectomy.

Cholecyst-enterostomy.

Choledochotomy.

OPERATIONS UPON THE LIVER.

Hepatotomy.—By the term “hepatotomy” is understood making an incision into the liver. This operation is indicated in the following classes of cases :—(*a*) In cases of hepatic sup-puration ; and (*b*) in cases of cystic disease of the liver, especially in hydatid disease.

The liver may be approached either through the abdominal or thoracic walls. The abdominal operation will be first de-scribed.

Position.—The patient is placed in the dorsal position, or lying somewhat on the sound side, if it is proposed to make an incision on the lateral aspect of the trunk. A hard sandbag or pillow should be placed underneath the lower dorsal region of the spine, so as to lift forward the liver and so make the organ rise nearer the parietal wound. The surgeon stands usually on the right side of the patient, and his assistant on the left.

Special instruments.—Exploring syringe or aspirator, needles (large fully-curved), cautery.

The abdominal operation.—The operation of hepatotomy may be divided into four stages, namely—

(a) *Parietal incision.*—An incision about 3 in. in length is made over that portion of the liver which is supposed to be the seat of the abscess. It may be necessary to puncture with an exploring needle or the needle of an aspirator before this can be determined. The incision usually commences at the costal margin, and extends downwards. This incision is deepened until the peritoneal cavity has been opened. If the inflammation has caused obliteration of that part of the cavity which lies between the affected part of the gland and the abdominal wall, the peritoneum is left untouched, but this condition is of rare occurrence in cases of hepatic suppuration.

(b) *Exposure of liver, incision of wall of abscess, and evacuation of pus.*—The liver lies exposed in the bottom of the wound after the peritoneum has been divided, and the margins of the parietal incision held aside. The adjacent portion of the peritoneal cavity is packed with flat sponges, so as to avoid septic contamination when the abscess is opened.

The location of the pus can usually be determined, either by the presence of a swelling on the surface of the liver, or by the presence of fluctuation. If there is any uncertainty as to the position of the abscess, the exploring syringe should be used.

The situation of the hepatic abscess having been determined, an incision about $1\frac{1}{2}$ in. in length, and parallel to the external wound, is made in the hepatic substance over the abscess. When the abscess has been reached, all hæmorrhage is arrested from any hepatic vessels which may require ligature, and then the opening is dilated with the finger or a pair of dressing forceps, and the pus allowed to escape. As the pus is escaping, the assistant should be directed to press the anterior abdominal walls against the liver, so as to prevent pus passing into the peritoneum. In some cases it will be found convenient to pass the forefinger into the cavity of the abscess and to hook the gland forwards. When the pus has been evacuated, the interior of the abscess cavity is examined with the finger so as to determine whether any other abscesses are present. If any are found, the intervening tissue is broken down with the finger, and the contents allowed to escape. The interior of the cavity is next irrigated with an antiseptic solution, and the aperture temporarily plugged with a sponge.

(c) *Union of margins of hepatic incision to those of parietal wound.*—All sponges are removed from the peritoneal cavity, and the peritoneum in the region of the hepatic incision is well

sponged, or locally irrigated if much contamination has taken place.

Next the margins of the incision in the liver are united to those of the incision in the abdominal wall, by the insertion of a ring of interrupted silk sutures. Each suture is entered at the lower part of the incision in the liver, and traverses the hepatic substance until it emerges about half an inch from the margin, and then it is passed through the tissues of the abdominal wall and made to emerge one-third of an inch from the margin of the parietal wound. The sutures are introduced at intervals of about one quarter of an inch.

Just beyond the upper and lower extremities of the hepatic incision, a suture should be passed through the abdominal wall, then through the liver substance beyond the angle of the wound, and finally through the abdominal wall on the other side of the incision. When all these sutures have been inserted, they are tied and the ends cut short, the two sutures at the extremities being tied last. That portion of the wound in the parietes to which the margins of the hepatic incision are not attached, is closed in the usual manner.

(d) *Establishment of drainage.*—When the cavity of the abscess is not very large, the interior should be packed with a long strip of antiseptic absorbent gauze, one end of which protrudes from the external wound. This should be removed daily, and replaced by a similar strip. Some prefer to insert a drainage tube, one end of which passes out from the external wound. An objection to the employment of this, at least immediately after the operation, is that it allows venous oozing to take place from the walls of the abscess. Another objection, if the tube is too long or too stiff, is that the lower extremity may lacerate the walls of the abscess cavity during the movements of respiration; the aid of capillary attraction is wanting in the case of a drainage tube also.

Hepatotomy for hydatid cyst of the liver.—This operation does not differ essentially from that for “abscess.”

When the abdomen has been opened and the cyst exposed, the peritoneum in the neighbourhood is packed with flat sponges and the cyst wall incised. The contents are evacuated, and the margin of the cyst wall stitched to those of the parietal incision, and drainage established. Before suturing to the abdominal wall, an attempt should be made to remove the endocyst. This can often be pulled by seizing a portion of the cut margin and exerting traction. In these cases, as a rule, no septic complications are present.

Some surgeons have advised that after the cyst wall has been incised, and the contents evacuated, the cyst should be dropped back into the peritoneal cavity and the abdominal incision closed. The aperture in the cyst wall may or may not be closed. This method of treatment has not as yet become well established. There are several objections to its adoption, such as deposit of calcareous matter in the wall of the cyst, and the possibility of infection of the peritoneum with the parasite.

Excision of ribs to expose the convex or right lateral surface of the liver by a transthoracic operation.—*Indications.*—This operation is requisite in the following clinical conditions :—

(a) Subphrenic hydatid cyst which is not readily accessible through an abdominal incision.

(b) Subphrenic abscess which is not accessible through an abdominal incision.

(c) Abscess of the superior part of the liver which extends upwards towards the thorax.

Position.—The patient is placed lying somewhat on the left side, so to fully expose the lateral aspect of the right side of the chest. The surgeon stands on the right side of the patient, and the assistant on the opposite side.

Special instruments.—Periosteal elevator, small saw, bone forceps.

Operation.—A site is selected on that part of the thorax which overlies the most prominent portion of the swelling, and an incision 3 in. long, which may be lengthened if necessary during the later stages of the operation, is made parallel to the ribs. A rib is exposed, the structures attached to it separated, and then a portion of it is excised (see p. 489). The underlying costal layer of the pleura is next divided, and the pleural cavity opened, whereupon the air rushes inwards, and the lung on the corresponding side becomes collapsed. The layer of pleura which covers the subjacent portion of the diaphragm is now sought for and brought as far as possible into the wound, and an incision an inch or more in length is made in it. The margins of the incisions in the two layers of pleura (costal and diaphragmatic) are closely approximated and united by numerous fine silk sutures. In this stage of the operation it may in some cases be found necessary to aspirate the hepatic swelling and remove a portion of its fluid contents, so as to relax the diaphragm and the overlying pleura.

The diaphragm in the bottom of the wound is now incised, and sutures are passed through it so as to fix it to the margins

of the wound in the thoracic wall. By this means the pleural cavity of the affected (right) side is completely shut off from communication with the external atmosphere, and also from the swelling which is about to be incised.

An incision is now made through the hepatic or other tissue which is exposed at the bottom of the wound, and is deepened until the cavity of the abscess or hydatid cyst is reached. The contents are evacuated, and the cavity is treated in a manner similar to that described when the abdominal operation was under consideration.

The extremities of the incision in the thoracic wall may be closed with sutures if it is thought advisable, and drainage established by a tube.

Hepatectomy.—It is only during recent years that surgeons have successfully removed portions of the liver by operation. The operation has been called “resection of the liver,” or hepatectomy. In those cases in which portions of the liver have been removed, a fair amount of success has been met with, and it is to be hoped, by the introduction of improved details of technique, that this operation may become a recognised and justifiable one, since there are many affections of the liver which only admit of a cure being obtained by a complete and radical removal of the diseased tissue. All operations of this nature which involve the liver are limited to the removal of a portion of the organ, since it is not possible for a person to live when the entire organ has been taken away, even if this operation were possible from a merely operative point of view. The removal of portions of the liver can be effected according to one of the following methods, each of which has been used and recommended by surgeons of repute :—

Special instruments.—As for hepatotomy, and in addition a long elastic ligature and compressor for portal vessels.

Operation (a) *Fixation of the diseased portion of the liver in an abdominal wound, and application of an elastic ligature to its base, so as to cause sloughing of the parts distal to the ligature.*—An incision from 4 to 6 in. long is made through that portion of the abdominal wall which overlies the affected portion of the liver, commencing above at the costal margin and extending downwards in a vertical direction. This incision is deepened until the parietal peritoneum is reached, when it is divided for the entire length of the wound. All hæmorrhage from blood vessels in the incised abdominal walls is arrested, and then that portion of the liver which it is wished to remove is brought well into the wound, and made to protrude externally,

so that the base of the diseased part can be brought into good apposition with the margins of the wound in the abdominal parietes. A series of silk sutures is next passed through the liver substance, well beyond the diseased area, and then through the abdominal wall a short distance from the margins of the incision, so that when these are tied the liver is firmly fixed to the abdominal wall, and the diseased portion protrudes externally. That portion of the abdominal wound which lies below the protruded part of the liver is closed in the ordinary manner with silk sutures.

An elastic ligature is placed around the base of the protruded piece of liver, but distal to the ring of sutures which fix the organ to the anterior abdominal wall. This ligature is allowed to remain in position for three or four days, the area of the operation being protected by the application of aseptic dressings. About the third day the elastic ligature is replaced by a second one, which is more tightly applied, and, if requisite, this in its turn is also replaced by a still tighter one. By these means the portion of the liver which lies beyond the elastic ligature is made to undergo a necrotic change, and in a short time it becomes separated as a slough or mass of gangrenous tissue.

When the constricted portion has separated from its connection with the remainder of the liver, the base of the protruded portion will cicatrise and heal. The separation of the protruded portion may be hastened by the use of the actual cautery on the tenth or twelfth day after the application of the elastic ligature. If the gangrenous portion remains too long in connection with the liver, putrefactive changes are very liable to become established, and the abdominal wound, or the liver itself, may become the seat of suppuration.

(b) *Fixation of the diseased portion of the liver in an abdominal wound, and removal of the affected part after the liver has become adherent to the margins of the incision (operation à deux temps).*—The early stage of this operation is exactly similar to that of the preceding. The portion of the liver which it is desired to remove is fixed by its base to the margins of a wound in the anterior abdominal wall, where it is left for several days or more. When the liver has formed adhesions to the margins of the abdominal wound, the second stage of the operation is performed. The portion of the liver which protrudes is detached from the remainder of the gland, either by cutting it away with a knife or with a Paquelin's cautery. As the piece of liver is removed, the cut surface

should be covered with a sponge, and pressure applied so as to arrest temporarily any hæmorrhage which may occur, and to prevent the possibility of the entrance of air into the open mouths of the intrahepatic veins, and thereby to avoid air embolism. When the portion of the liver has been detached, the sponge pressure is relaxed, and all bleeding points upon the cut surface are ligatured with silk. After hæmorrhage has been arrested in this manner, the cut surface of the organ is irrigated

FIG. 132.—Resection of liver. Method of inserting sutures into the liver after a “wedge-shaped” portion has been removed. This diagram shows all the sutures in position before any have been tied. In this case the portion of the gland which has been resected has been from the antero-inferior margin, and the adjacent parts of the inferior and anterior surfaces of the left lobe.

so as to remove all traces of blood and débris, and then an aseptic dressing is applied, and is firmly fixed in position by strapping and a bandage. In order to avoid the exposure of a large cut surface of the liver, after the resected portion has been removed, it appears to me that in the second stage of the operation it would be preferable to resect the part of the liver which is to be removed, by the employment of a “wedge-shaped” incision, such as is described later.

If this form of incision in the liver were adopted, it would be possible to bring together the margins of the hepatic wound,

and fix them in apposition by the insertion of sutures. All fears of the occurrence of hæmorrhage and air embolism may thus be avoided. In all cases of exposure of a cut area of the liver, great care must be taken to prevent the entrance of air into the hepatic veins, since in these structures the venous blood pressure is negative, and air may be drawn inwards by suction.

Some authors have recommended that, after the portion of liver has been detached with the knife, the actual cautery should be applied to the cut surface, so as to arrest hæmorrhage and prevent the occurrence of air embolism. If it is wished to make use of the cautery, it appears to me to be preferable to remove the piece of the liver with the knife of a Paquelin's cautery, and so arrest all hæmorrhage as the operation proceeds. The objection to the use of the cautery in these cases is the necessary necrosis of charred tissue which must follow, and the liability to suppuration as the dead tissue is being separated or absorbed.

(c) *Removal of tumours and cysts from the liver by dissection, and subsequent closure of the wound in the liver by sutures, together with simultaneous closure of the abdominal incision.*—Tumours of the liver which are completely encapsuled, or hydatid and other forms of cysts which are embedded in the gland, may be removed by dissection. After the surface of that portion of the liver which contains the tumour or cyst has been exposed by an incision in the abdominal wall, the surrounding portion of the peritoneal cavity is packed with aseptic sponges, so as to avoid contamination of the peritoneum with blood or foreign material, or injury to the intestines, and then an incision is made into the hepatic substance, until the superficial portion of the tumour is exposed. The tumour or cyst is then separated

FIG. 133.—Compressor for hepatic artery and portal vein.

from the normal hepatic tissue by a process of careful dissection.

The circulation in the liver can be controlled during operations upon it by an assistant passing the forefinger into the foramen of Winslow, and placing the thumb on the anterior aspect of the gastro-hepatic omentum and then exerting pressure. A more convenient method of compressing the hepatic artery and the portal vein is by use of the instrument depicted in Fig. 133.

The surfaces of the wound left by the removal of the cyst

FIG. 134.—Resection of liver. Same as Fig. 132, but with all the sutures tied and the ends cut short.

or tumour are approximated and fixed in apposition by the insertion of a number of interrupted deep sutures. The external wound is closed in the usual manner.

(d) *Excision of a portion of the liver by the employment of a "wedged-shaped" incision.*—The abdomen is opened and the liver exposed as in the previous operation. The diseased area is defined, and an elastic ligature made to encircle the base a short distance beyond the limits of the growth. If this cannot be conveniently done, an assistant ought to pass his hand into the abdominal cavity in such a manner that his forefinger is in the foramen of Winslow and the thumb on the anterior surface of the gastro-hepatic omentum, in front of the hepatic artery

and the portal vein, or the instrument shown in Fig. 138 is used. By exerting compression upon both these structures, the circulation can be controlled.

The affected portion of the liver is then removed, according to the method shown in Figs. 132 and 134.

When the wound in the liver has been completely sutured, and its margins brought together, the gland is dropped back into the abdominal cavity, all blood sponged away, and the incision in the parietes closed in the ordinary manner. If there is much venous oozing from the region of the hepatic wound, the involved area is packed with a long tampon of aseptic gauze, one end being brought out through the external wound. This is removed at the expiration of twenty-four or forty-eight hours.

Ruptures and wounds of the liver.—*Indications.*—Rupture of the liver is occasionally met with as the result of violence. The symptoms presented by the patient are those of internal hæmorrhage and shock, and often the presence of a fluctuating swelling in the right lumbar and hypochondriac regions. Whenever a diagnosis is made that a patient is suffering from a rupture of the liver and consequent intra-peritoneal hæmorrhage, an operation for the relief of the injury should be performed with as little delay as possible. It will often happen that the exact nature and extent of the intra-abdominal injury will only be established when the abdomen has been opened.

Operation.—The peritoneal cavity should be opened by an incision 3 to 4 in. long, above the umbilicus, and either in the right linea semilunaris or a little to the right of the linea alba. The former incision should be adopted in those cases when the physical signs definitely locate the injury in the right hypochondriac region. When the peritoneal cavity has been opened, all blood, blood clot, or bile should be quickly sponged away, and the margins of the abdominal wound widely retracted, so as to expose as much as possible of the surfaces of the liver. If the injury is not then visible, the hand should be introduced into the peritoneal cavity, and passed upwards to the right and to the left, so as to palpate the surfaces of the liver, and thus detect any solutions of continuity upon its surface and into its substance. When these have been detected, the margins of the wound should be held widely apart, and the injured part of the viscus lifted up towards the surface, and the surrounding viscera protected from injury and contamination by flat marine sponges or cellular pads. The margins of the tears or rents should first be sponged dry, and any torn and bleeding blood vessels picked up with pressure forceps and ligatured. Next

the margins of the rupture are brought into apposition, and fixed by the insertion of a series of interrupted sutures of medium silk or catgut. Each suture is inserted with a curved needle, entering one-third of an inch from the margin of the tear, extending through the liver substance beyond the bottom of the rupture, and having its exit a similar distance beyond the opposite margin. The sutures should be one-sixth of an inch apart, and all should be introduced before any are tied. When all the sutures have been inserted, they are tied in such a manner that the margins of the rupture are brought into complete and moderately firm apposition, whilst the hepatic substance is not torn by the sutures themselves. When the repair of the injuries has been completed, the surfaces of the injured portion of the liver and the adjacent peritoneum are carefully sponged so as to remove all traces of blood and bile, and then the flat sponges or pads are removed. When there is much hæmorrhage at the time of operation, it can be controlled until the bleeding vessels are secured, by grasping the structures in the gastro-hepatic omentum between the finger and thumb, or applying the hepatic compressor illustrated in Fig. 133. The wound in the parietes is finally closed in the usual manner, but if oozing of blood continue, owing to extensive laceration, the bleeding area may be packed with a long strip of gauze, one end of which is brought through an angle of the parietal wound left unsutured for the purpose.

If the injury to the liver is extensive, it may be necessary to enlarge the original incision in a 7-shaped manner, so as to enable the operator to obtain a good exposure of the damaged parts.

Perforating wounds of the liver, such as stabs and gunshot wounds, which necessitate operative interference, are usually most conveniently treated by enlarging the external wound until the injured portion of the viscus is laid bare, and then treating it by the method above described.

OPERATIONS UPON THE BILIARY SYSTEM.

Cholecystotomy. — Cholecystotomy implies making an incision through the wall of the gall bladder. The gall bladder is attached to the inferior surface of the liver, and lies in a wide groove just to the right of the quadrate lobe. The fundus of the sac lies immediately behind the costal cartilage of the right ninth rib, and at this point often projects slightly beyond the inferior margin of the liver, especially when it is distended.

Indications.—The operation is performed for the following conditions, namely—(a) Gall stones within the gall bladder; (b) collections of pus or fluid in the gall bladder, which are due to impaction of gall stones, or to inflammatory conditions of the mucous membrane of the gall bladder dependent upon septic micro-organisms; (c) the removal of gall stones impacted in the cystic duct.

Special instruments.—Cholecystotomy forceps and scoop, needles (fully curved and half curved), aspirating needle.

Position.—The patient is placed in the dorsal position, and near the right side of the table. The surgeon stands on the right side of the patient, the chief assistant directly opposite to him.

Operation.—The operation may be divided into the following stages, namely—(a) *Parietal incision.*

FIG. 135.—Cholecystotomy.
Line of parietal incision.

—An incision from 3 to $3\frac{1}{2}$ in. long is made through the anterior abdominal parietes, commencing above at the margin of the ninth right costal cartilage, and extending downwards towards the right pubic spine. The incision is deepened until the peritoneal cavity has been opened, care being taken to avoid notching the liver or injuring the intestines. When the rectus muscle has been exposed, its fibres are separated in a vertical direction, as few fibres as possible being divided with

the scalpel. The incision should be so situated that it lies over the right rectus abdominis muscle, about half an inch to three-quarters of an inch from its external margin.

(b) *Finding of gall bladder and bringing it into external wound.*—If the gall bladder does not at once protrude, the margins of the incision are held apart with retractors, and the fingers of the right hand are introduced into the peritoneal cavity, and the viscus is sought for on the lower aspect of the liver. In many cases it will be found to be enlarged, and often attached to the adjacent structures by strong adhesions. When the situation of the organ has been made out, it is brought into the wound, any adhesions which prevent this being divided if requisite.

(c) *Incision of gall bladder, and removal of calculi and other pathological collections from interior.*—If the gall bladder is very large, owing to distension with fluid, part of the fluid contents

may be evacuated by aspiration with an aspirator. The margins of the perforation with the aspirator needle are seized with forceps, and an incision about half an inch in length made through the wall of the gall bladder on the convexity of the fundus, and passing through the seat of perforation, if one has been made. Before making this incision, the surrounding portion of the peritoneal cavity is packed with flat sponges, so as to prevent contamination as far as possible. The interior of the viscus is next examined with the finger, and the size, shape, and locality of any gall stones which may be present made out. These bodies are then removed, either with cholecystotomy forceps or a scoop, whichever may be the more convenient. When the gall bladder has been emptied, the cystic duct is examined from the interior of the viscus, and if any calculi are present they are removed. The interior of the organ is washed out by irrigation, and a small sponge placed in the aperture, which will serve as a temporary plug, and prevent the escape of fluid into the peritoneum. The sponges which have been placed around the organ in the peritoneal cavity are removed, and the course of the extra-hepatic bile ducts examined with the finger. If these do not contain calculi, and are otherwise normal, the region of the gall bladder is thoroughly cleansed by sponging, and the margins of the incision in the fundus attached to those of the parietal wound.

(d) *Fixation of margins of wound in gall bladder to those of parietal incision, and closure of the other portion of the external wound.*—The margins of the gall bladder incision are brought into apposition with those of the upper portion of the parietal wound, and fixed there by the insertion of sutures. The sutures are best introduced in the following manner:—On each side of the incision in the gall bladder a row of sutures are inserted, one-sixth of an inch apart, each suture passing through the fascial, muscular, and serous strata of the abdominal wall, and then through the wall of the gall bladder into its interior. At the upper and lower extremities a suture is passed from one side of the parietal incision to the other, taking up the gall bladder just beyond the incision by passing through its muscular and serous coats. The portions of the parietal wound above and

FIG. 136.—Cholecystotomy forceps.
—ANDERSON.

below the sutured part of the gall bladder are closed by sutures in the usual fashion. All the sutures are introduced before any are tied. When all the sutures have been inserted, they are tied, and the sponge plug removed from the interior of the gall bladder, and a small rubber tube passed down into the cavity of the viscus, so as to act as a drain. If silk be used for the sutures, each suture should be cut with long ends, so that they can be readily removed when union has taken place. If they are cut short and the gall bladder is septic, considerable trouble may result and a fistula. Chromicised catgut may be used in place of silk.

The above operation is the ordinary one adopted in the removal of gall stones from the interior of the gall bladder and the cystic duct. It will be seen, however, that a fistula is established, through which the bile from the gall bladder drains for a time. In favourable cases this fistula closes within three to five weeks. On account of the formation of a fistula, many surgeons call the operation "cholecystostomy."

Cholecystendysis. — In favourable cases, where the walls of the gall bladder are in a perfectly healthy condition and at the same time are thick and muscular, it is possible to close the incision in the gall bladder at the time of operation, and to drop the viscus back into the peritoneal cavity and then to close up the external wound. When this is done, two tiers of sutures should be inserted, the first uniting the mucous membrane, and the second the serous and muscular coats. This form of operation is called "cholecystendysis," or "ideal cholecystotomy."

Cholecystectomy. — Removal of the gall bladder is known as cholecystectomy. The operation has been performed for the following conditions: — (a) Localised malignant growths of the gall bladder; (b) rupture and perforation, when the region of the neck of the gall bladder has been involved, or the injury has been extensive; (c) in cases of mucous fistula associated with obliteration of the lumen of the cystic duct; (d) many cases in

FIG. 137. — Cholecystostomy scoop.

which the gall bladder has been long distended with gall stones and retained secretions, its walls thinned and in places ulcerated. In the latter class of case, the period of rest in bed is shortened, there is no annoying biliary fistula for a time, and the risk of further formation of gall stones is minimised. The risks of the operation do not appear to be greater than when a fistula is established; (e) gangrene of the gall bladder; (f) in cases of membranous or phlegmonous cholecystitis.

Operation.—The instruments and the early stages of the operation are similar to those employed in cholecystotomy. When the peritoneal cavity has been opened, the gall bladder is separated from the inferior aspect of the liver by dividing the peritoneum on each side of the groove in which it lies, and also around its fundus in the region of the anterior inferior border. When this has been done, the organ is separated from the liver with the fingers, all bleeding vessels which are met with being tied as the operation proceeds. By this means the gall bladder is separated from the liver until the cystic duct is reached. With a needle on a handle, a moderately stout silk ligature is passed around the cystic duct, and tied. The duct is then cut across and the gall bladder removed. If possible, the mucous membrane of the divided portion of the cystic duct should be removed by scraping, or cauterised with carbolic acid 90 per cent., especially when the gall bladder is the seat of an inflammatory process. When this has been done, the margins of the wound in the peritoneum on the inferior surface of the liver are, if possible, brought together and fixed in apposition by the insertion of a continuous silk suture. The stump of the cystic duct is covered over with a flap of peritoneum as the continuous suture is being inserted. The area of operation is cleansed by careful sponging or local irrigation, and the parietal wound closed in the usual manner. If there is much bleeding, it may be necessary to pack the wounds with plugs of antiseptic gauze, the ends of which are brought out in an angle of the external wound which is left open for the purpose.

Cholecyst-enterostomy.—Cholecyst-enterostomy is an operation which has for its object the creation of an artificial communication between the gall bladder and the intestine, usually the duodenum.

Indications.—The operation of cholecyst-enterostomy appears to be indicated in the following conditions:—

(a) In all cases where the common bile duct is permanently obstructed or occluded by adhesions, inflammatory processes, or malignant growths, the cystic duct remaining patent. The

forms of new growth include those which are primary in the common bile duct and those which commence in the head of the pancreas and spread to it by direct extension. In cases where the common bile duct is occluded as the result of secondary malignant growths, it is not advisable to perform the operation.

(b) In all cases of complete division of the common bile duct as the result of injury or operative measures.

(c) In cases of chronic biliary fistulæ which cannot be cured by the performance of a plastic operation, or in which the fistulæ are due to obstruction of the common bile duct, and are not amenable to direct surgical interference.

(d) In all cases of perforation of the common bile duct which result from an ulcerative process, and in which choledochostomy cannot be performed.

(e) In cases of kinking of the common bile duct which are due to the presence of fibrous adhesions, and cannot be remedied by operation.

Special instruments.—Intestinal clamps and small “anastomosis button” (Murphy’s).

Position.—The patient is placed in the dorsal posture, the surgeon stands on the right side of the patient, and the assistant on the left.

Operation.—The operation may be divided into the following stages:—

(a) *Parietal incision.*—An incision is made in the right linea semilunaris, commencing at the edge of the ribs and extending downwards for 2 or 3 in. This is extended until the peritoneal cavity has been opened.

FIG. 138.—Method of inserting “purse-string suture” into intestine in the operation of cholecyst-enterostomy.—After MURPHY.

(b) *Finding and delivery of gall bladder and duodenum, and union of same.*—The gall bladder and the duodenum are drawn into the wound; a needle threaded with 15 in. of silk is inserted into the duodenum, directly opposite the attachment of the mesentery; and at a point near the head of the pancreas a stitch is taken through the entire bowel, one-third of the length of the incision to be made; the needle is again inserted one-

third the length of the incision from its outlet, in a line with the first, and embracing the same amount of tissue as the first. A loop 3 in. long is held here, and the needle is inserted in a similar manner, making two stitches parallel to the first in the reverse direction, and one-fourth of an inch from it, coming out at a point near the insertion of the needle. This forms a running thread, which, when tightened, draws the incised edge of the bowel within the cup of the button. A similar running thread

FIG. 139. — Cholecyst-enterostomy. Method of holding male portion of anastomosis button for insertion.

FIG. 140. — Cholecyst-enterostomy. Method of holding female portion of anastomosis button for insertion.

is inserted in the gall bladder. An incision, which is two-thirds of the diameter of the button to be used, is now made in the intestine, care being taken to avoid cutting the running thread when making the incision; the male half of the "button" is slipped in, the running thread tied firmly around the central cylinder, and then the button is given to an assistant to hold with forceps, so as to prevent it slipping into the cavity of the bowel. An incision is now made in the gall bladder, the same length as the one in the intestines, between the two rows of suture. The gall stones and fluid contents of the gall bladder

are removed; the female half of the "button" inserted, and the running thread tied. The forceps are then removed, the two halves of the "button" are held between the fingers and slowly pressed together. A sufficient degree of pressure must be used to bring the serous surfaces of the gall bladder and intestine firmly in apposition and compress the tissues. The elastic pressure of the spring cup of the "button" produces a pressure atrophy of the tissues embraced by it, and leaves an opening

FIG. 141.—Cholecyst-enterostomy. Gall bladder and duodenum, showing two halves of anastomosis button introduced, with the "purse-string" sutures tied, and ready for fixing together.—After MURPHY.

which is larger than the "button." When the "button" is liberated, it passes on through the bowel, and is voided per anum, from eight to fourteen days after the operation.

(c) *Closure of external wound.*—This is closed in the usual manner by the insertion of interrupted silk sutures. One or more tiers may be introduced.

Choledocholithotomy — choledochotomy.—This operation has for its object the removal of one or more calculi from the interior of the common bile duct, in cases in which an

obstruction to the flow of bile along this canal has been established, or in which severe symptoms result from the impaction.

Position.—The patient is placed in the dorsal position. The operator stands on the right and the assistant on the left. A large sand-bag, or “shaped lumbar block,” should be placed underneath the lower dorsal region, so as to throw the lower dorsal and lumbar spine forwards. This “aid” very much facilitates manipulations in connection with the common bile duct.

Operation.—In performing the operation, the abdominal cavity is opened by an incision which is made either a little to the right of the linea alba, commencing above immediately below the ensiform cartilage, or through the right rectus muscle, a little internal to its outer margin, commencing just below the costal margin. It is not always possible to make an exact diagnosis as regards the seat of the impacted calculi, and when this is the case it is better to make the incision in the linea semilunaris. When the abdominal cavity has been opened, the course of the biliary tract is examined with the finger; the gall bladder should be examined first, then the cystic duct, and then the common bile duct, both as it lies in the gastro-hepatic omentum and in its course behind the first part of the duodenum, and where it lies between and behind the head of the pancreas and the left aspect of the second portion of the duodenum. In many cases, placing the examining finger in the foramen of Winslow will be found to be of diagnostic value, since in this position a considerable extent of the common bile duct can be palpated, and if there is a calculus in its interior its position can be at once made out. When a stone is discovered in the common bile duct, the gastro-hepatic omentum and the common bile duct are drawn into the abdominal wound. The peritoneal cavity around these structures is packed with sponges, and an incision is made in the common bile duct over the calculus, this incision being parallel to the long axis of the duct. Through this incision the impacted calculus is extracted, care being taken to damage the walls of the duct as little as possible. In order to facilitate the removal of the calculus, it is found in some cases to be advantageous to break up the stone with crushing forceps and to extract it in several fragments. When the stone has been removed, the area of the operation is thoroughly sponged, and the margins of the incision in the common bile duct are then approximated and fixed in apposition by the insertion of two tiers of fine sutures. The sutures

through the mucous membrane should be of fine catgut, and those through the superficial layers of peritoneum either silk or catgut. Silk sutures passed through the mucous membrane favour the development of another gall stone. The first unites the mucous membrane, and the second the muscular and serous coats. If the peritoneum which forms the anterior layer of the gastro-hepatic omentum has been dissected from the bile duct, it may be united separately from the muscular walls of the

(Seen from above.)

common duct, in which case three tiers of sutures will be requisite. In many cases of this operation, it will be found advisable to pack the region of the incision in the common duct with a strip of aseptic gauze, and to bring out the end of this strip through an angle of the abdominal wound, which is left open for the purpose. This strip is removed after one or two days, and if there is no sign of leakage from the duct, the abdominal wound is entirely closed. The strip of gauze is replaced by a similar one when any small quantity of fluid escapes. It is sometimes found that the impacted calculus lies

behind the duodenum, and then it is necessary to lift up this structure and open the common bile duct, as it lies behind it. If the calculus is a small one, or the common bile duct is considerably dilated, an attempt may be made to manipulate the calculus into the duodenum, by forcing it along the duct and through the orifice on the biliary papilla.

CHAPTER VII.

OPERATIONS UPON THE SPLEEN.

THE following are the operations which may be performed upon the spleen :—

SPLENECTOMY.

SPLENOTOMY.

TREATMENT OF RUPTURES AND WOUNDS.

Removal of the spleen, or splenectomy.—In this operation the spleen is removed through an incision in the anterior or antero-lateral abdominal wall.

Indications.—Removal of the spleen is indicated in the following clinical conditions :—(a) Certain cases of rupture of the organ, due to some form of injury, such as a blow upon the abdomen, or a stab, or to spontaneous rupture, in which hæmorrhage cannot be arrested by milder measures; (b) some forms of cystic affections which are not amenable to drainage; (c) some forms of “movable” or “wandering” spleen, in which the viscus cannot be retained in position by a suitable belt, or cannot be fixed in its usual place by a surgical operation; (d) some forms of hypertrophy, either simple or malarial in nature, which cannot be relieved by other measures; (e) occasional cases of suppuration or inflammation. Malignant disease of the spleen and leukæmic hypertrophy appear to contra-indicate removal.

Location.—The spleen is a solid viscus, situated upon the anterior aspect of the posterior abdominal wall. It lies in the left portion of the epigastric region and upper part of the left hypochondrium, about one-third being in the former and two-thirds in the latter. It lies obliquely, its upper extremity being nearer the middle line than the lower. The diaphragm and the posterior inferior margin of the left lung and pleura intervene between it and the inner surfaces of the ninth, tenth, and

eleventh ribs. The splenic artery enters, and the splenic vein emerges, from the hilum. The viscus is attached to the left margin of the stomach by the gastro-splenic omentum, and to the left kidney by the lieno-renal ligament, which two unite above in the phrenico-splenic ligament, thus attaching it to the diaphragm. The tail of the pancreas lies in close relation to the hilum.

Special instruments.—Large clamp forceps, sponge-holders, needle on handle with blunt point.

FIG. 143.—Transverse section of body, to show relations of spleen to adjacent viscera. (Seen from below.)

a. Spleen.
b. Left kidney.
c. Right kidney.
d. Right lobe of liver.
e. Pancreas.

f. Stomach.
g. Aorta.
h. Inferior vena cava.
j. Vertebra.

Position.—The patient is placed in the dorsal position, or, when the antero-lateral incision is employed, lying slightly upon the right side. The surgeon stands on the left side, and the first assistant directly opposite to him.

Operation.—Removal of the spleen may be divided into several stages, which are—

(a) *Parietal incision.*—An incision from 4 to 5 in. in length is made either in the left linea semilunaris, or below and parallel to the left costal margin. In the latter case the incision

commences immediately outside the outer border of the left rectus abdominis muscle, and 1 in. below the costal margin, and extends downwards and backwards in a line parallel with the costal margin to the interval between the last rib and the iliac crest. Whichever incision is made use of, the wound is deepened until the various strata of the abdominal wall have been divided and the peritoneal cavity opened. In most instances it is advisable to adopt the incision in the linea semilunaris, but in fat and emphysematous people with deep chests the other incision will enable the operator more easily to get at the pedicle and apply a ligature to it.

(b) *Separation of adhesions and delivery of spleen.*—The abdominal cavity having been opened, the intestines, including the splenic flexure of the colon, are pushed downwards and towards the right, and covered with flat sponges. If any adhesions are present, they are defined, surrounded with ligatures in two places, and divided between. When all adhesions have been divided, the spleen is carefully lifted up from its position underneath the ribs into the external wound. Its pedicle is then defined. Usually this will be found to be broad and extensive, and have important connections. It consists of four laminae of peritoneum—the two layers which form the gastro-splenic omentum and the two layers of the lieno-renal ligament.

(c) *Ligature of pedicle and removal of spleen.*—The structures which require careful attention in ligature of the pedicle are the blood vessels; in the gastro-splenic omentum are the gastro-epiploica sinistra artery and vein; and in the lieno-renal ligament, the splenic artery and vein. Care must be taken to avoid damage to the large splenic vein. In order to do this the spleen should be turned towards the right, so as to expose its posterior surface; the positions of the artery and vein are defined, and the needle pushed between the two, and its point made to emerge through the gastro-splenic omentum half-way between the stomach and spleen. The needle is threaded with a double ligature of silk, and withdrawn. The two ligatures thus introduced are locked and tied, one around one-half of the pedicle and the other around the other half. Finally, the second ligature is made to surround the entire pedicle, and is again tied in a knot. When the pedicle is very broad, it will be necessary to transfix it in several places, and to tie the ligatures in the form of a locked chain.

During the passage of the pedicle needle through the posterior aspect of the pedicle, great care must be taken not to transfix

the tail of the pancreas, and in tying the ligature not to include any part of this structure. In some cases it may be necessary to apply, first of all, ligatures to the splenic artery and vein, an inch from the hilum of the spleen, and then by dissection to separate the tail of the pancreas from its connections with the hilum of the spleen and the lienorenal ligament.

The ligatures having been applied to the pedicle, this is cut through on the splenic side of the ligatures and about two-thirds of an inch from them, and the spleen removed. The stump of the pedicle is carefully sponged, in order to render evident any bleeding points, which are at once ligatured. When all hæmorrhage has been arrested, the stump of the pedicle is returned into the abdomen, and the exposed portion of the peritoneal cavity freed from blood, etc., by careful sponging with an aseptic sponge. All sponges are next removed from the peritoneum, and the intestines are allowed to fall back into their usual position.

(d) *Closure of external wound.*—This is effected in the usual manner by the insertion of several tiers of sutures. If there is much oozing, it is advisable to pack the space from which the spleen has been removed with a long strip of aseptic gauze, one extremity of which is brought out through an angle of the external wound, which is left open for the purpose.

The chief danger in the operation of splenectomy is the liability to the occurrence of severe hæmorrhage. The most favourable cases are those in which the viscus is removed for injury.

Splenotomy, or incision of the spleen.—This operation may be necessary in some cases of abscess of the viscus in which the inflammatory process has extended to the surrounding tissues and caused the formation of numerous adhesions. An incision is made through the abdominal wall over the most prominent part of the inflammatory swelling, until the abscess cavity is reached.

The general peritoneal cavity is then shut off with sponges, the viscus brought into the wound, and the cavity opened and the contents evacuated. A sponge is then inserted into this incision, those shutting off the surrounding peritoneal cavity removed, and the edges of the incisions in the spleen and parietes united with interrupted sutures, the wound packed with gauze, and dressing applied.

Ruptures and wounds of the spleen.—*Indications.*—Rupture of the spleen is occasionally met with as the result of violence. The symptoms presented by the patient are those of internal

hæmorrhage and shock, and the presence of a fluctuating swelling in the left lumbar and hypochondriac regions. Whenever a diagnosis is made that a patient is suffering from a rupture of the spleen and consequent intra-peritoneal hæmorrhage, an operation for the relief of the condition should be carried out with as little delay as possible. Often the exact nature of the intra-abdominal injury will only become apparent after the peritoneal cavity has been opened.

Operation.—The peritoneal cavity should be opened through an incision 3 to $3\frac{1}{2}$ in. long, above the umbilicus, and situated either a little to the left of the middle line or in the left linea semilunaris. The latter incision should only be adopted when the physical signs definitely locate the injury in the left hypochondrium or the left lumbar region. When the peritoneal cavity has been opened, all blood or blood clot should be quickly sponged away, and the hand introduced and passed upwards and towards the left into the left hypochondrium, in order to palpate carefully the surfaces of the spleen, so as to detect any solution of continuity upon its surface and in its substance. When these are located, the entire viscus is brought into the parietal wound—a proceeding which is facilitated by exerting strong traction upon the left margin of the incision with a large abdominal retractor—and the extent of the injury made out. If the viscus is severely lacerated, or a portion almost detached, the entire organ should be removed according to the method already described (p. 164). If the injuries do not involve more than one-half the thickness of the organ, and there are no detached portions, the rents should be closed by the insertion of a series of sutures, each suture entering one-third of an inch from the margin of the tear, extending through the splenic substance to just beyond the bottom of the tear, and having its exit a similar distance beyond the opposite margin. Moderately thick silk or catgut should be used for this purpose. The sutures should be one-sixth to one-eighth of an inch apart, and all should be inserted before any are tied. When all the sutures have been inserted, they are tied in such a manner that the margins of the tear or rupture are brought into complete and firm apposition, whilst the splenic substance is not torn by the sutures themselves. Hæmorrhage from any torn branches of the splenic artery or vein, or from the splenic substance, can be controlled during the suturing by an assistant grasping the gastro-splenic omentum and exerting pressure on the splenic artery and vein, especially the former. When any large branches of the splenic artery are torn across, each should be picked up separately with

pressure forceps and ligatured with silk. When the repair of the injuries has been completed, the surface of the viscus and the adjacent peritoneum are sponged free of blood, the spleen is returned into the abdominal cavity, and the parietal wound closed in the usual manner. Essential elements in obtaining success in this operation are—first, early operation, and secondly, control of the circulation through the splenic artery by digital pressure until the suturing is completed. I have performed this operation with complete success recently on a boy of 10 years, who had sustained an extensive double rupture of the spleen.

Some surgeons recommend that when the region of the injury to the splenic tissue has been exposed, it should be thoroughly packed with strips of gauze. I do not see any objection to this method of treatment, but think the suture method is the better, as it more completely arrests hæmorrhage, and does not leave a large wound which has to close by granulation.

Perforating wounds of the spleen, such as stabs and gunshot wounds, which necessitate operative interference, are treated by enlarging the external wound until the injured viscus is exposed, and then treating it according to the methods described above. In many cases of perforating wounds of this kind to the lumbar region, it will be found advisable to commence, as described above, by opening the abdomen from the front, since, if the wound is deep and extends forwards, a more satisfactory and complete exposure of the injured parts is obtained.

CHAPTER VIII.

OPERATIONS UPON THE URINARY SYSTEM.

THE following operations upon the urinary system will be described, namely—

OPERATIONS UPON THE KIDNEYS.

Nephrolithotomy.

Nephrotomy.

Nephrectomy.

1. Lumbar operation. 2. Abdominal operation.
Nephrorrhaphy.

OPERATIONS UPON THE URETERS.

Ureterotomy.

1. Lumbar. 2. Pelvic. 3. Vesical.

Ureteroplasty.

Ureterectomy.

Uretero-ureteral anastomosis.

1. End-to-end. 2. End-in-end. 3. Lateral.

Uretero-vesical anastomosis.

OPERATIONS UPON THE URINARY BLADDER.

Puncture of the bladder.

1. Suprapubic. 2. Rectal. 3. Perineal.

Litholapaxy (lithotrity).

Suprapubic cystotomy.

Lateral lithotomy.

Median lithotomy.

Treatment of rupture of the bladder.

OPERATIONS UPON THE URETHRA.

External urethrotomy (Wheelhouse's operation).

Internal urethrotomy.

For the treatment of ruptured urethra.

OPERATIONS UPON THE KIDNEYS.

Nephrolithotomy.—Nephrolithotomy is an operation which has for its object the removal of a calculus from a kidney. It

is usually carried out through an incision in the lumbar region of the affected side, and on this account is sometimes called "lumbar nephrolithotomy."

Indications.—The performance of the operation is indicated in all cases in which there is reason for thinking that a calculus is situated either in the kidney substance itself or in the pelvis, when this calculus gives rise to severe symptoms, and cannot be got rid of by other measures.

Special instruments.—Retractors (wide), lithotomy forceps and scoop, long straight round needle on handle, long-bladed tenotome, small bladder sound (No. 3), syringe, and drainage tube.

Position.—The patient is placed in the semiprone position, lying upon the sound side with the back near the edge of the operation table. A moderate-sized sandbag or hard pillow is placed underneath the loin. The surgeon stands behind the patient, and the chief assistant on the opposite side.

Operation.—The operation of nephrolithotomy may be conveniently divided into the following stages, namely—

(a) *Parietal incision.*—An incision is made in the lumbar region, from 3 to 4 in. in length at first, which is parallel to the lower border of the last rib and half an inch below it; it commences in front and terminates at the outer border of the erector spinæ group of muscles, usually about 2 in. or $2\frac{1}{2}$ in. from the dorsal spine. Care must be taken to make certain of the position of the last rib by counting them from above, in order to avoid the pleura. It occasionally happens that the twelfth rib is very short and rudimentary, and the eleventh is mistaken for it. In these cases, if the incision is made half an inch below the eleventh costal arch, the lower portion of the pleura will in nearly every case be injured. The incision is deepened, the fasciæ being first divided and then the muscular strata. The posterior fibres of the external oblique and the anterior fibres of the latissimus dorsi—both of them almost vertical in direction—are divided first; next, the internal oblique and the posterior

FIG. 144.—Lumbar nephrectomy and nephrolithotomy. Position of patient and line of external incision. The dotted lines show the lower border of the last rib, the iliac crest, and the outer border of the erector spinæ.

aponeurosis of the transversalis muscle, which in the inner portion of the incision splits to enclose the quadratus lumborum; and, finally, the fascia transversalis, and if requisite the outermost fibres of the quadratus lumborum, care being taken at this stage to avoid injury to the peritoneum. The subcostal

| h. Small intestine. | r. Erector spinae. |

nerve and a branch of the upper lumbar artery may be exposed in making the incision, and if met with they are pulled upwards with a retractor, so as to preserve them from injury.

(b) *Exposure of the kidney.*—When the fascia transversalis has been divided, the perinephric fatty connective tissue appears in the bottom of the wound. This is broken down with the tip

of the finger or dissecting forceps, and by this means the posterior aspect of the kidney is laid bare. Large flat retractors are now used to pull upwards and downwards the margins of the parietal incision, so as to more fully expose the surface of the kidney. If the kidney is movable in the perinephric tissue, it may tend to fall forwards, and so render its full exposure somewhat difficult. This difficulty may be avoided by directing the assistant to press backwards the anterior abdominal wall with the clenched fist of one or both hands. By this means the kidney can often be forced into the bottom of the wound.

(c) *The examination of the kidney for the detection of the calculus.*

—The kidney being supported from the front, either by the assistant or the hand of the surgeon, the whole of the posterior aspect is systematically palpated with the finger, and any irregularities or points of resistance noted. If a calculus is present, it can often be felt as a resistant body through the kidney substance. If nothing can be felt abnormal on the posterior aspect, the forefinger of the surgeon is passed round the external border of the organ, and the anterior surface examined. If nothing indicating the presence of a calculus is discovered by these manipulations, the kidney may be grasped between the forefinger and the thumb, and each part of it squeezed, and any point of increased resistance noted. Next, the pelvis of the organ is examined from behind, the patient being again turned into the semiprone position, if his position has been changed. If any hard or resistant area has been discovered during the digital examination, a needle on a handle is taken and forced into the hard spot so as to determine the presence or absence of a calculus in the suspected part of the viscus. If the above digital examination fails to locate the calculus, the kidney is fixed in the bottom of the wound by

FIG. 146.—Broad abdominal retractor.

pressure from in front, and then its substance explored with the needle on a handle by puncturing the kidney methodically from upper to lower end. The perforating portion of the needle ought not to be longer than 2 or $2\frac{1}{2}$ in. At each thrust of the needle the point should be directed towards the hilum. If all

FIG. 147. — Calculus forceps for extracting calculi from the pelvis of kidney.

these measures fail, an incision should now be made into the posterior surface of the gland with a long-bladed tenotome or scalpel. This incision is inclined inwards and forwards, until the cavity of one of the calyces has been opened. The interior of the calyces and the pelvis of the kidney is now examined, first with a small steel sound, and then with the forefinger of the surgeon. This examination should be made in a systematic manner, commencing above and gradually working downwards until the commencement of the ureter has been reached. In young and thin patients the examination and treatment may sometimes be facilitated by carefully bringing the kidney out of the wound on to the surface of the abdominal wall. By one or other of these measures a calculus, if within the kidney or its pelvis, will generally be discovered. It has been advised that the pelvis of the kidney should be opened by incising its posterior surface, instead of incising the kidney substance. A wound of the pelvis of the kidney, however, is thought by some to be more frequently followed by a urinary fistula than when the incision is made through the renal substance, though hæmorrhage is more likely to follow the latter procedure. The stone, having been located by one of the above methods, must be removed.

(d) *Removal of the calculus.*—If the kidney has not already been incised in the detection of the stone, an incision is made directly over the calculus with a scalpel or bistoury, the forefinger is passed into the wound, and the stone lifted out if possible. When this cannot readily be removed with the finger,

a small pair of lithotomy forceps or a scoop is passed down to the region of the calculus, which is then seized and extracted. If the calculus is a branching one, it should be broken up into several fragments, each one being removed separately, to avoid unnecessary injury to the renal tissue. When the stone is within the pelvis of the kidney, it may be removed either through the incision in the renal tissue, or through an incision made through the posterior aspect of the pelvis itself; if the stone obstructs the commencement of the ureter, difficulty is often experienced in its extraction. By careful manipulation, however, it can usually be successfully removed.

When all fragments of the stone or stones have been removed, the wound in the kidney and the entire area of operation is irrigated with an antiseptic solution, so as to remove all blood, portions of calculus, and débris. If any distinct bleeding points become apparent, they are ligated with fine silk. General venous oozing can be controlled and arrested by packing with tampons of gauze.

(e) *Treatment of the wound in the kidney, and the closure of the parietal incision.*—The wound in the kidney is packed with tampons of gauze, one extremity of each being brought into the angle of the abdominal incision, or in suitable cases it may be sutured. A rubber drainage tube is next passed down to the region of the incision into the kidney, but not into it, and fixed in position by suturing it to the margin of the parietal incision. Next, the external wound is closed by the insertion of sutures of silk or silkworm-gut, except at the angle where the drainage tube and the end of the gauze tampon have been brought out, and aseptic dressings applied. The tampons of gauze can usually be removed at the end of twenty-four hours.

Nephrotomy.—The term nephrotomy implies the exposure of the kidney and the making of an incision into its substance.

Indications.—The operation is indicated in the following conditions of the organ:—(a) In cases of suppuration of the kidney, due to renal tuberculosis or other pathological condition; (b) in certain cases of hydronephrosis and pyonephrosis; (c) in calculus suppression of urine; (d) in the treatment of certain cases of simple or hydatid cyst of the kidney.

The term exploration of the kidney is sometimes used to indicate the exposure of the organ by a surgical operation, when it is wished to make a digital examination without making an incision into the renal substance.

Operation.—The instruments necessary for the performance of the operation, and the individual stages of the operation itself,

are similar to those described in the preceding operation up to the stage of exposure of the gland. An incision is then made into the diseased portion of the organ, and any fluid collections which may be present are evacuated. Drainage is nearly always requisite after this operation.

Nephrectomy.—The removal of a kidney by the performance of a surgical operation is called nephrectomy. The organ may be removed, either through an incision made in the lumbar region of the diseased side, which does not open the peritoneal cavity, or through an incision made in the anterior abdominal wall which opens the peritoneum. The former operation is known as “lumbar nephrectomy,” and the latter “abdominal nephrectomy.” The choice between these two operations is a matter of opinion, but it is certainly best to treat all suppurative conditions by the lumbar method, whilst large growths and cysts must be removed through the abdominal incision, since the space between the last rib and crest of the ilium is limited. Should this space, however, prove too small in treating extensive suppurating affections of the kidney, the lumbar incision may be continued forwards and downwards, and room thus gained.

Indications.—Removal of the kidney may be necessary in the following pathological conditions, namely—(a) Certain cases of hydronephrosis, pyonephrosis, suppurative and cystic affections which are not amenable to treatment by nephrotomy; (b) some cases of ureteral and renal fistula; (c) diseased conditions of a floating kidney which cannot be remedied by other means; (d) some cases of severe injury of one kidney; and (e) certain cases of malignant disease of the kidney. Unless it is known that the opposite kidney is not seriously diseased, and is capable of performing its normal functions, in no case would nephrectomy be justifiable. When secondary deposits have formed in other organs, as a result of a primary malignant disease of one kidney, removal of the affected organ should not be attempted. As regards the choice of method, in most instances the lumbar operation is to be preferred, the abdominal variety being carried out only in cases of large solid tumours of the kidney or in cases of extensive cystic disease.

1. **Lumbar nephrectomy.**—*Special instruments.*—Volkman's spoon, clamp forceps, and pedicle needle.

Position.—The patient is placed in a semiprone posture, lying on the sound side, with the back near the edge of the table, and a hard pillow or sandbag underneath the loin, so as to separate the last rib and iliac crest as far as possible. The surgeon stands behind the patient, and the assistant on the other side opposite

to him. A second assistant stands on the right hand of the surgeon.

Operation.—The operation may be divided into the following stages, namely—

(a) *Parietal incision.*—The incision is made in the lumbar region, parallel with and about half or two-thirds of an inch below the inferior margin of the last rib. It measures in length from 3 to 5 in., according to the obesity of the patient and the size of the organ to be removed, commences in front, and terminates at the external border of the erector spinæ muscle. The various strata of the abdominal wall are divided as in the operation of “nephrolithotomy,” until the posterior aspect of the kidney is exposed. In some cases it will be necessary to make a second incision, so as to enlarge the field of operation and facilitate the manipulations of the surgeon. This can be best effected by making a short vertical incision downwards, commencing about an inch external to the posterior angle of the oblique wound.

(b) *Enucleation of the kidney.*—In most cases the organ should be separated from its surrounding perinephric pad of fatty connective tissue. This may be accomplished in many instances by the fingers, but it occasionally happens when there has been much inflammation—especially in old-standing suppurative cases—that this cannot be done. If the kidney cannot be separated from its surroundings in this manner, it is advisable to open the capsule proper, and then enucleate it. Usually, however, small portions will remain behind, adherent to the fibrous capsule. In very difficult cases, where the exact extent of the renal tissue cannot be made out, the removal may be effected either by cutting with a scalpel or a pair of curved scissors. Sometimes a combination of these methods enables the surgeon to separate the kidney from its surroundings. When the enucleation has been completed, the organ is lifted up in the wound by an assistant, so as to allow of the separation and ligature of the pedicle.

(c) *Separation and ligature of the pedicle.*—The margins of the parietal wound are held well apart with wide flat metal retractors, whilst the surgeon defines the pedicle and separates it into two parts, an upper containing the blood vessels, and a lower the ureter alone. The portion of the pedicle containing the renal vessels should be carefully separated from the surrounding tissues for a short distance towards the abdominal aorta. This will give more room for the application of the ligature, and there will be less chance of it slipping afterwards. This having

been done, a pedicle needle threaded with medium silk is passed between the two halves of the pedicle, and tied around that portion which contains the blood vessels, the point of application being an inch or more from the hilum of the kidney. A pair of clamp forceps is then placed on the lower half of the pedicle, or ureter.

(d) *Removal of the kidney.*—The kidney is lifted up into the parietal wound by an assistant, who takes great care not to exert traction upon the blood vessels; and then the surgeon, with scissors, divides both portions of the pedicle, the upper half, about two-thirds of an inch on the distal side of the ligature—that is to say, in most cases at the hilum of the kidney—and the lower half, on the kidney side of the clamp forceps. The organ is then removed. When it is difficult to separate the upper half of the pedicle, owing to extensive inflammatory adhesions, a small button of renal tissue may be left on the distal side of the ligature, so as to prevent any tendency which it might otherwise have to slip, owing to the nearness of the ligature to the cut surface of the pedicle stump. The pedicle is now sponged dry and examined, and if any bleeding points become visible, they are picked up with artery forceps and ligatured with silk.

(e) *Treatment of the ureter and closure of the external wound.*—When the ureter is apparently healthy, a ligature is applied to it, and it is dropped back into the wound. The entire field of operation is next irrigated, and the parietal incision closed by the insertion of sutures of silk-worm gut, which are so introduced that they approximate as far as possible the incised surfaces. If there is much oozing, or there has been recent inflammation, a drainage tube is passed down into the bottom of the wound, and one extremity brought out through an angle of the external incision which has been left open for the purpose. If the ureter is dilated and filled with pus or tuberculous material, its interior should be well scraped with a small, sharp Volkmann's spoon; and then, if all the diseased tissue has been got rid of, a ligature may be applied as low down as possible, the part distal to this removed, and the ligatured end dropped back into the wound. When, however, the ureter is extensively diseased, as in some cases of tuberculous disease of the kidney, or in calculous pyonephrosis, it should either be removed at the same time as the kidney or at a later period (see section on "Ureterectomy," p. 189). The external incision is then closed as before. If all traces of pus cannot be satisfactorily removed, and it is decided not to attempt removal of the ureter, the open end of the ureter is

brought into the angle of the parietal incision, and fixed there by a few points of suture, the other parts of the incision being closed in the usual manner.

2. Abdominal nephrectomy.—*Instruments.*—The instruments are the same as those required for the “lumbar” operation.

Position.—The patient is placed in the dorsal position on the operating table, the surgeon stands on the affected side, the chief assistant opposite to him, and a second assistant at his right hand.

Operation.—The stages of the operation are—

(a) *Abdominal incision.*—An incision from 4 to 6 in. in length, according to the size of the diseased kidney and the thickness of the abdominal walls, is made in the linea semilunaris of the affected side, the centre of the incision being at the level of the umbilicus. This is deepened until the peritoneal cavity has been opened for the entire length of the incision. The hand of the surgeon is then introduced through the aperture, and the size and connections of the diseased organ made out, and, in addition, the kidney of the opposite side is examined by passing the hand over to that side. If the patient is fat, considerable difficulty may be experienced in distinguishing the healthy kidney, owing to the large amount of perinephric fat which surrounds it. If it is found advisable and possible to remove the diseased kidney, and the one on the opposite side is present and healthy, the operation is proceeded with.

FIG. 148. — Abdominal nephrectomy. Line of external incision.

(b) *Exposure of the kidney.*—The small intestines and omentum are pushed over towards the opposite side of the abdomen, and held out of the way by the insertion of one or more flat sponges. The margins of the external wound are held apart with retractors, and the outer aspect of the colon on the diseased side defined. The parietal peritoneum, on the outer side of the colon and just beyond it, is divided, or, better, torn with the fingers until an aperture 2 or 3 in. in length has been made. By tearing the tissues with the fingers, the peritoneum on the anterior aspect of the posterior abdominal wall, together with the colon, is lifted up and separated from the anterior surface of the kidney and its blood vessels. A number of blood vessels may require ligature during this stage.

(c) *Separation and ligature of the pedicle.*—When the anterior aspect of the kidney and its blood vessels have been exposed, the vessels are separated from the adjacent tissues with the finger, and a blunt aneurysm needle passed around them, 1 in. or more from the hilum of the kidney. The needle is withdrawn, and the ligature securely tied. The ureter is next either seized with clamp forceps or ligatured.

(d) *Removal of the kidney.*—The ureter is severed on the kidney side of the clamp, the blood vessels are divided, and then any connections between the kidney and the surrounding tissues are broken down with the finger. The organ can now be lifted out of the wound, and removed. If it is doubtful whether the ligature on the blood vessels will hold, a second one ought to be applied a short distance nearer the aorta, taking care to avoid the inferior vena cava on the right side. All bleeding points in the field of operation are picked up with artery forceps, and ligatured. If the ureter is healthy, a ligature is applied to it and it is dropped back; but if it is dilated and filled with pus or tuberculous material, it is best either to remove it or to scrape away as much of the purulent matter as possible, and then to make a small incision in the lumbar region, and bring it out through this opening, the margins of its open end being sutured to the external wound.

(e) *Treatment of the peritoneum, and closure of the external wound.*—The space from which the kidney has been taken is thoroughly sponged out and irrigated with an antiseptic lotion (or hot salt solution), so as to remove all blood clots, etc., and render evident any bleeding vessels which may have escaped ligature. When this has been done, the peritoneum and the intestines are allowed to fall back into their former positions, and the external wound is closed in the usual manner. The wound in the peritoneum on the outer side of the colon must be sutured, and if there is considerable oozing of blood from the field of operation, a second incision should be made in loin, and through it a drainage tube inserted.

Nephrorrhaphy, or Nephropexy.—The operation which has for its object the fixation of an abnormally movable kidney to the posterior abdominal wall, is called nephrorrhaphy, or nephropexy, the former term being the one which is more commonly used.

Indications.—The operation is indicated in cases of movable or floating kidney which are not amenable to less severe measures, and are a source of serious annoyance and inconvenience to the patient, or are even a danger to life.

Special instruments.—As for nephrotomy, and in addition thick catgut or kangaroo tendon and a large curved needle.

Position.—The positions of the patient, surgeon, and assistants are the same as in lumbar nephrectomy.

Operation.—The stages of the operation are—

(a) *Parietal incision.*—An incision 3 in. in length is made in the lumbar region, parallel to and half an inch below the inferior margin of the last rib. It commences at the outer border of the erector spinæ, and extends downwards and forwards. This is deepened, each muscular layer being divided parallel with its fibres, until the posterior surface of the kidney has been reached, or at least until the perinephric fat becomes visible.

(b) *Exposure of the kidney.*—The loose perinephric fat and connective tissue is torn away, until the posterior aspect of the kidney has been laid bare. It is advisable to remove entirely the layer of fat which lies between the kidney and the fascial covering of the posterior abdominal muscles. Some difficulty may be experienced in finding the kidney, especially in those cases in which the organ has a distinct mesonephron. It can, however, usually be made to protrude in the bottom of the wound, by the assistant making strong pressure from the front so as to force the organ backwards. When it has been found by any of these methods, it is brought into the bottom of the lumbar incision, or even brought entirely outside, and its posterior aspect thus thoroughly exposed. Some surgeons have advised that a portion of the capsule should be detached from this surface; others, it should be scarified or painted with a 90 per cent. solution of carbolic acid. Both procedures have for their object the creation of firm adhesions as the result of plastic inflammation. Separation of a portion of the capsule is, I think, the most reliable. A vertical incision is made through the fibrous capsule of the kidney along the middle of its posterior surface, and two transverse incisions, each an inch in length, at right angles to and at each extremity of the vertical incision. By these means two oblong flaps are marked out. The capsule thus demarcated is separated from the posterior aspect of the kidney, and each flap turned towards the corresponding margin of the kidney, and a portion of the posterior surface of the kidney laid bare.

(c) *Fixation of kidney to tissues in lumbar region.*—Four to six sutures of silk or chromic gut are passed through the reflected capsule and posterior surface of the kidney. Each suture is passed through the muscular and fascial layer of the abdominal wall at the margins of the wound, pierces the turned back kidney

capsule, and penetrates about half an inch into the thickness of the organ. The upper sutures pass through the upper edge of the fibrous tissue capsule, the transversalis fascia, and the muscles, and are tied to them; the lower sutures are similarly passed through and tied to the lower edges of the cut structures; and the intermediate sutures are passed through both edges of the divided capsule, fascia, and muscles, and lace all up together.

If the periosteum on the internal aspect of the last rib (or the last two ribs) can be readily made accessible, the upper sutures which are used for anchorage of the kidney should be passed through this tissue before they are tied. This will help to fix the organ more securely.

(d) *Closure of external wound.*—The silk or chromic gut sutures are cut short, and then the various structures divided in the parietal incision are brought into apposition by the insertion of sutures in the usual manner. It is advisable, in a few cases of nephrorrhaphy, to pass a drainage tube of moderate size to the bottom of the wound and leave it there for a few days, in order, if possible, to incite increased plastic inflammation.

OPERATIONS UPON THE URETERS.

Anatomical considerations.—The ureter is a hollow tube with a small lumen, which commences at the pelvis of the kidney and terminates in the bladder close to the vesicula seminalis. It usually measures about 10 in. in length, and throughout its entire course it lies in the extra-peritoneal tissue, behind the parietal peritoneum, on the anterior aspect of the posterior abdominal and pelvic walls. It may be divided into two portions—an abdominal, which commences at the lower part of the pelvis of the kidney, and passes downwards, lying upon the psoas magnus muscle, and terminating at the brim, where it crosses and lies upon the common iliac artery; and a pelvic, which commences where the tube crosses the common iliac artery, and then passes obliquely downwards, forwards, and inwards, until it reaches the base of the bladder, the wall of which it pierces. The pelvic part crosses the internal iliac and obturator vessels, and as it reaches the bladder it is surrounded by a plexus of vesical and prostatic veins. At this point it is crossed on its inner side by the corresponding vas deferens, and lies in front of and close to the upper part of the vesicula seminalis. In the female, the ureter lies on the outer side of the cervix uteri and the upper portion of the vagina. The uterine artery

crosses the anterior aspect of the ureter close to its termination. The abdominal portion of the ureter is somewhat the longer, and measures from 5 to 6 in., whilst the pelvic part is from 4 to 5 in.

Varieties of operation.—From a surgical point of view, the ureter may be exposed by an operation either in the abdominal or pelvic portions of its course, and it may be approached either through the peritoneum or outside this membrane. The former operations are called “trans-peritoneal” and the latter “extra-peritoneal.” As regards regions, the ureter may be attacked from the loin—lumbar operation; from the iliac region—iliac operation; from within the bladder—vesical operation; and through the antero-lateral abdominal wall, by an incision through the corresponding linea semilunaris—abdominal operation. By a combination of the lumbar and iliac operation, the entire course of the ureter may be exposed.

Other methods have been suggested and occasionally practised, such as rectal, sacral, perineal, and vaginal. For a discussion of these, the student is referred to a larger treatise. The operations mentioned will be found to meet nearly all practical requirements.

The different methods of exposing the ureter will now be described, and afterwards the various surgical procedures which can be performed, and the main indications for them.

Lumbar operation.—*Position.*—The patient is placed lying on the sound side with a hard pillow or sandbag underneath the loin. The surgeon stands behind the patient, and his assistant on the opposite side.

Operation.—An oblique incision 4 in. long is made, commencing 1 in. above the anterior superior spine of the ilium, and extending upwards and backwards to a point 1 in. below the lower margin of the last rib and over the lateral margin of the erector spinæ muscle (about 2 in. from the spinous processes of the vertebra). The skin fascia and muscular strata are divided as in exposure of the kidney, and the lumbar and transversalis fascia laid bare. These are carefully incised for the entire length of the incision, and then the perinephric fatty tissue in the upper portion of the wound broken down with the finger or dissecting forceps, until the lower part of the kidney is visible. The pelvis of the kidney is then defined on the inner side, and the ureter traced downwards as far as the brim of the pelvis, where it crosses the common iliac artery. Care must be taken to avoid opening the peritoneum in exposing the abdominal course of the ureter. This can generally be done by keeping

close to the outer margin of the quadratus lumborum muscle. In order to obtain a good exposure of the deeper structures, after division of the muscular and fascial strata, the margins of the wound should be held wide apart by large abdominal retractors (Fig. 146). If further exposure of the ureter be required, the incision should be prolonged forwards parallel with Poupart's ligament.

Iliac operation.—*Position.*—The patient is placed in the dorsal decubitus, the surgeon stands on the affected side of the patient, and the assistant on the opposite side.

Operation.—An incision $3\frac{1}{2}$ in. to 5 in. long is made, commencing three-quarters of an inch above and a little external to the pubic spine, and extending upwards and backwards parallel with Poupart's ligament and the iliac crest to a point the same distance above the iliac crest and 2 in. behind the anterior superior spine of the ilium. The skin, fascial, and muscular strata of the abdominal wall are incised until the extra-peritoneal tissue is exposed. Care must be taken not to injure the deep epigastric artery in the inner angle of the incision. If it is exposed it should be pulled inwards with a retractor. With the fingers the peritoneum is separated from the anterior aspect of the fascia in

FIG. 149.—Exposure of ureter by iliac method.

A. Incision in iliac operation.

B. Incision in inguinal operation.

the iliac fossa, until the external iliac artery is laid bare. This is then followed inwards until the ureter is found as it crosses the brim of the pelvis. The inner margin of the wound is next strongly retracted, the peritoneum peeled from the lateral wall of the pelvis, and the ureter traced downwards, forwards, and inwards until it reaches the base of the bladder. The terminal part of the ureter is recognised by the appearance of the vas deferens and the vesicula seminalis in the inner part of the wound, and the bladder by the reddish strands of muscular fibres. Gentle traction on the first exposed pelvic portion of the ureter assists in fully exposing the deeper part at its junction with the bladder. Considerable hæmorrhage may be met with in exposing this terminal portion, owing to injuries to the veins of the vesical and prostatic plexus.

In both of these operations the ureter can generally be readily

recognised, especially when in pathological condition it is enlarged owing to the presence of a calculus in its interior, or dilated owing to some obstruction in some part of its course. In order to expose the entire ureter, the above two incisions may be entirely combined, as in Fig. 150.

Trans-peritoneal operation.—*Position.*—The patient, surgeon, and assistants are the same as in the previous operation. The position of the parietal incision varies according to whether it is desired to expose the abdominal or the pelvic portions of the ureter. It is best made about a half to three-quarters of an

FIG. 150.—Exposure of entire course of ureter by an ilio-lumbar incision.

a. Oblique incision.
b. Curved incision.

inch from the corresponding side of the middle line, in the position shown in Fig. 151, for the pelvic part of the tube; and through the linea semilunaris when it is wished to deal with the abdominal portion.

For exposure of abdominal part.—An incision 4 in. long is made in the corresponding linea semilunaris, commencing 1 in. above the umbilicus, and extending 3 in. below it. The abdominal walls are incised, and the peritoneal cavity opened, as in the operation for abdominal nephrectomy. The position of the portion of the ureter it is wished to expose being determined upon, an incision about 2 in. long is made through the parietal peritoneum on the anterior aspect of the posterior abdominal

wall, and well on the outer side of the ureter. The ureter having been defined, it is dealt with according to one of the methods described in the succeeding sections. It is requisite, in order to obtain a good view of the ureter, that the abdominal viscera should be held towards the opposite side by wide retractors and flat sponges.

For exposure of pelvic part.—An incision $3\frac{1}{2}$ in. to 4 in. long is made half an inch to one side of the middle line. The different strata of the abdominal wall are divided, and the peritoneal cavity opened. The coils of intestine and the omentum are held aside, and the course of the ureter within

the pelvis determined. An incision 2 in. long is then made through the parietal peritoneum of the pelvis parallel with the course of the ureter, and a little to the outer side. The peritoneum is then dissected up, and the course of the ureter laid bare. Care must be taken in this procedure not to allow the assistant to retract the ureter along with the peritoneum. Very deep and wide abdominal retractors, of the shape shown in Fig. 146, are necessary for the performance of this operation.

FIG. 151.—Incisions to expose ureter by “trans-peritoneal method.”

- a. For abdominal part.
- b. For pelvic part.

Comparison of the extra-peritoneal and intra- or trans-peritoneal methods, and general indications as to choice of operation.

—The *intra- or trans-peritoneal* method is the only one which can be adopted where it is desired to establish an anastomosis of the ureter with either the bladder or a portion of the alimentary canal; otherwise, in all cases of calculi, strictures, valvular formations of the mucous membrane, and when excision of the whole or part of the ureter is necessary, one of the extra-peritoneal methods should be made use of. A considerable number of patients, in whom operations upon the ureter are requisite, have a septic condition of the urine, or there is ulceration of the walls of the ureter; and in all these, *trans-peritoneal* operations are almost invariably followed by the development of peritonitis, on account of either contamination of the peritoneum at the time of operation, or by extension of septic urine

to it afterwards along the course of the incision. All cases in which it is necessary to incise the wall of the ureter are very liable to have an escape of urine for a short time along the line of incision, and if this has been performed by the *trans-peritoneal* method, it usually happens that the escaped urine sooner or later enters the peritoneal cavity, and gives rise to serious complications.

In my opinion, the extra-peritoneal operations, in the majority of instances, give quite as good if not a better view of the ureter; the ureteral operations can be carried out with as great ease; and in every case satisfactory drainage can be easily, readily, and effectively established. These are the reasons for so strongly advocating the adoption of extra-peritoneal operations, with the exception of those cases where the establishment of anastomosis is necessary.

Vesical operation.—The interior of the bladder is exposed by performing a preliminary “suprapubic cystotomy,” according to the method given on p. 200, and then the opening of the ureter into the bladder on the affected side is incised, and sufficiently enlarged to carry out whatever may be necessary on the lower part of the ureter. This operation is of especial value in cases of impaction of a urinary calculus in the lower part of the ureter, and in constrictions of the ureteral opening consequent upon cicatrisation following a previous ulceration. When these operations are performed, the patient should always be placed in the inclined or “Trendelenberg” position.

Ureterotomy.—This operation comprises the making of an incision through the wall of the ureter, and is performed in the majority of instances for removal of urinary calculus, impacted in the lumen of the ureter (uretero-lithotomy), occasionally for removal of a valve of mucous membrane which interferes with the ordinary permeability of the canal of the ureter, and also as the first part of the operation of “ureteroplasty” (p. 187, *q.v.*).

Position.—The position of the patient varies according to the part of the ureter it is wished to expose. When the lumbar and abdominal portions are sought, the patient is placed in the lateral position; and when the pelvic or vesical parts are the seat of disease, he is placed in the dorsal position, with the pelvis raised.

Operation.—The operation can be carried out in the following stages:—

(a) *Exposure of the ureter.*—The ureter is exposed by incising the abdominal walls, according to one of the methods already described.

(b) *Separation and fixation of the portion of the ureter it is wished to deal with.*—When the seat of impaction of the urinary calculus or the locality of other pathological condition has been determined, the ureter is separated by careful dissection from the peritoneum in front and the fascia behind, for a distance of about 3 in., and then this portion is brought towards the parietal wound and held in position by an assistant. Usually this is quite easy, as the ureter is surrounded by loose connective tissue containing a variable amount of fat; but when inflammation has occurred, considerable difficulty may be experienced in effecting the separation.

(c) *Incision of ureter.*—When a calculus is immovably impacted within the canal, an incision is made on the postero-external aspect of the ureter, opposite the position of the calculus, and sufficiently long to permit of easy extraction without laceration of the walls. Extraction is best carried out by the aid of long-handled, narrow-bladed calculus forceps. If the calculus can be moved upwards, an incision of sufficient length is made through the postero-external wall of the dilated ureter, about an inch or a little more above the seat of arrest of the calculus. The calculus is then removed with forceps or scoop, as above. The calculus having been removed, the course of the ureter is investigated with a bougie or sound, in order to detect the possible presence of a second calculus, and also to determine the permeability of the canal. When the object of operation is the treatment of a valve of mucous membrane, the position of this valve is first determined, and the postero-external wall of the ureter then incised in a vertical direction, parallel with the long axis of the tube, and immediately on the kidney side, for an inch or a little more. The projecting fold of mucous membrane is then incised and cut away.

(d) *Treatment of the wound in the ureter.*—Whenever the parts operated upon are not the seat of septic inflammation or supuration, the urine is not septic, and the ureteral walls have not been lacerated, the incision in the ureter should be carefully closed by the insertion of a series of fine silk (00) sutures. If, however, the area of operation is in a septic condition, when the urine is septic, or when the ureteral walls have been lacerated, it is better not to attempt to close the opening, but to establish free drainage through a convenient portion of the parietal wound.

(e) *Closure of parietal wound.*—If the opening in the ureter has been closed by sutures, a roll of gauze or a small drainage tube should be passed down to the seat of the sutures,

and the other extremity brought out through the nearest part of the external wound. The other portions of this wound are then closed by tiers of sutures.

When, however, the opening in the ureter has been left partially or completely unsutured, a large rubber drainage tube should be passed down to the ureteral opening and brought out at a convenient portion of the parietal wound. A sufficient portion of the external wound is left open so as to allow very free drainage, and the remainder closed by careful suturing.

When a calculus is impacted immediately above the opening of the ureter into the bladder, or a fibrous constriction exists at this opening, a suprapubic cystotomy is first performed in order to expose the part of the ureter affected. Next, the opening of the ureter on the affected side is brought into view and incised in an upward and outward direction. In the case of impacted calculus, this is removed with suitable forceps through the opening thus made. The vesical and ureteral wound so made is then carefully sutured, care being taken to leave a good canal for the subsequent passage of urine. If the pathological condition is a stricture or stenosis of the ureteral opening into the bladder, the opening is first enlarged by incision, as above, and then the mucous membrane of the adjacent portion of the bladder is dissected up for a short distance and then sutured to the margins of the enlarged opening. This procedure prevents subsequent contraction of the opening.

Ureteroplasty.—This operation consists in restoring the lumen of a constricted ureter to its normal size by the performance of a plastic procedure.

Indications.—Stricture and stenosis of the ureter dependent upon changes in its walls, such as stenosis and fibrous constriction after ulceration, and a similar condition following an injury.

Operation.—The ureter is exposed by one of the methods already described, and the affected portion separated from its connective tissue and peritoneal surroundings. A vertical incision is then made through the wall of the ureter, extending the entire length of the stenosed part, and also for a short distance above and below it. Next, the margins of this incision are first separated, and then approximated by traction, until they come together in a direction at right angles to the long axis of the tube. The two extremities of the original incision in the wall of the ureter are now fixed together by insertion of a fine silk suture, and subsequently the other parts of the incision in a like manner. The details of the suturing are exactly similar to those described in connection with "pyloroplasty" (p. 64, *q.v.*).

When the operation upon the ureter has been completed, a small roll of gauze is passed down to the sutured area, and the other end brought out through an angle of the parietal wound. The other portions of this wound are then closed by insertion of tiers of sutures.

Ureterectomy.—By the term ureterectomy is understood removal of either the whole or part of the ureter. It may be carried out at the same time as and in connection with removal of the kidney, or at a later period. The term “resection of the ureter” is generally given to the operation which comprises excision of a segment of the ureter, and subsequent anastomosis either of the two cut ends, or, when it is the distal portion which is removed, with the bladder or a part of the intestinal canal.

Indications.—(a) Tuberculous disease of the ureter, when the kidney of the corresponding side is also the seat of extensive tuberculous disease.

(b) Chronic ureteral fistula, which cannot be cured by other means.

(c) Chronic inflammation and suppuration in connection with the ureter, following calculous disease, or, in occasional cases, chronic ureteritis, the result of extension of the suppurative process from the kidney or bladder.

(d) Malignant growths of the ureter when they have not too extensively involved the adjacent tissues, and when these are not accompanied by the formation of secondary growths.

All operations for removal of the ureter ought to be carried out by the extra-peritoneal method, except in those cases where it is done as part of an operation for removing a malignant tumour of the bladder. In this latter class suprapubic cystotomy is first performed, and in removal of the bladder growth the peritoneal cavity is usually of necessity opened.

Position.—The patient is placed in the lateral position, lying on the sound side; the surgeon stands on the affected side, and his assistant opposite to him. It is advisable to have a second trustworthy and capable assistant, on account of the large wound requiring considerable retraction.

Operation.—Removal of the ureter may be divided into the following stages:—

(a) *Parietal incision and exposure of the ureter.*—The ilio-inguinal incision is first made as in Fig. 150, and at later stages it may be continued backwards or forwards as may be found requisite, and the course of the ureter exposed.

(b) *Separation and removal of the ureter.*—The ureter having been exposed, it is separated from the overlying peritoneum

and the underlying and surrounding connective tissues by careful dissection, opening of the peritoneum at any point being especially avoided. When the kidney is removed at the same time, it is first freed and separated by dissection, and also by ligature of the blood vessels which pass to its hilum. The ureter can then be clamped at two places in its upper part, divided between the two clamps, and the kidney removed. The lower part of the ureter is separated down to the junction with the bladder, a ligature is applied close to the bladder so as to surround it, a clamp placed half an inch on the proximal side, and then the ureter is severed close to the ligature, and removed. When the lumen of the ureter contains purulent matter, the region of the bladder should be carefully packed with gauze, which may absorb any fluid exudation, and so tend to avoid contamination of the pelvic portion of the field of operation with septic material. Next, the mucous membrane in the interior of the stump of the ureter is canterised, either with strong carbolic acid (90 per cent.) or with the actual cautery, and the fibrous and muscular coats sewn over with two or three points of silk suture, introduced by Lembert's method. Whenever the mucous membrane of the stump is thickened and infiltrated, all softened tissue should be scraped away with a small Volkmann's spoon before canterisation, and sutured.

(c) *Treatment of the wound.*—The entire wound should be thoroughly irrigated with an antiseptic solution, and then two rubber drainage tubes inserted. One of these is placed in the lumbar and iliac portions of the wound, and the other in the pelvic part. The portions of the parietal wound between, above, and below the places of exit of the drainage tubes are finally closed by sutures.

The operation of simultaneous removal of the kidney and ureter is known as "nephro-ureterectomy." It should only be done in those cases where the general condition of the patient is sufficiently good to allow of so severe an operation. Often it will be found more advisable to remove the ureter at a future operation. Removal of the ureter at a second operation is usually called "*secondary ureterectomy*."

Resection of the ureter.—This operation is indicated in—(a) Cases of hard fibrous strictures or stenosis of the ureter which cannot be treated by ureteroplasty; (b) in injuries of a small segment of the ureter, when associated with severe laceration of the ureteral wall; (c) involvement of a small segment of the ureter in a malignant growth, which can be removed by operation.

Operation.—The stenosed portion of the ureter, or the part involved in a malignant growth, is exposed by one of the methods already described, then the diseased portion is excised by cutting across the tube transversely in two places, and taking away the part thus separated. When this has been done, one of the methods of “uretero-anastomosis” is carried out in order to complete the operation, and so establish the patency and continuity of the ureteral canal (p. 191 *et seq.*).

Ureteral anastomosis.—An anastomosis may be established between an open end of a ureter and the distal portion of the same ureter, between it and the urinary bladder, and between it and a segment of the alimentary canal. These are called respectively, “uretero-ureteral anastomosis,” “uretero-vesical anastomosis,” and “uretero-intestinal anastomosis.” The two first operations are those usually practised, uretero-intestinal anastomosis having been found to be almost invariably followed by septic conditions of the ureter and kidney, which ultimately proved fatal.

Indications for “ureteral anastomosis.”—

(a) When resection of a portion of the ureter has been performed for stenosis, ulceration, local destruction, or malignant growths. (b) After accidental or intentional division, during the performance of abdominal or pelvic operations. (c) After injuries which have caused division of the ureter. These latter may be either intra- or extra-peritoneal, and perforating or non-perforating. Before deciding which variety of ureteral anastomosis is most advisable, and whether it shall be carried out by an

extra-peritoneal or an intra- or trans-peritoneal operation, every individual case must be carefully considered, and the advantages or disadvantages of the proposed operation discussed. As a general rule, it may be stated that most cases which require ureteral anastomosis can be most conveniently operated upon by the trans-peritoneal method, and that uretero-ureteral anastomosis can only be made use of when the course (and not the lower extremity) of the ureter is the seat of lesion, whilst uretero-vesical anastomosis must be practised

FIG. 152. — Uretero-ureteral anastomosis (Van Hook's lateral method).

- a. Distal part of ureter.
- b. Proximal part of ureter.
- c. Suture.

when the lower portion of the ureter next to the bladder has been taken away.

Uretero-ureteral anastomosis.—This form of anastomosis can be carried out either by suturing together directly (transversely or obliquely) the cut open ends of a divided ureter, by invaginating the upper end into the lower, or by closing the open end of the distal segment and implanting the open end of the proximal segment in the side of the first part of the distal segment. When the ureter above its lower extremity is the seat of disease or injury which necessitates ureteral anastomosis, the operation of lateral anastomosis appears to have been followed by the best results, according to the records of cases which have been published.

The actual establishment of uretero-ureteral anastomosis is effected by the following procedures, after the two ends of the ureter

FIG. 153.—Uretero-ureteral anastomosis.

have been made ready for joining together. (*a*) A circular ligature is placed around the proximal end of the distal segment about one quarter of an inch from the cut extremity (Fig. 152, *a*).

(*b*) With a pair of fine-pointed scissors a longitudinal incision, twice the length of the diameter of the ureter, is made in the wall of the distal portion of the ureter, one quarter of an inch below the circular ligature (Fig. 152, *a*), and an incision vertical in direction is also made in the free end of the proximal segment for a distance of one quarter of an inch (Fig. 152, *b*). This second incision is said to ensure patency of the canal and avoid development of a stricture. (*c*) Two very small sewing-needles are threaded on one strand of fine catgut, and passed through the wall of the proximal end of the ureter one-eighth of an inch from the free end, from within outward, the needles being about one-eighth of an inch apart, and the same distance from the cut end of the ureter. (The loop of catgut thus introduced between the needles grasps the upper end of the ureter, Fig. 152, *b*.) These needles are now carried through the aperture or slit in the side of the distal part of the ureter, and down the tube for half an inch, when they are pushed through the wall of the duct side by side. (*d*) Traction is now made on the catgut loop which passes through the wall of the ureter, so as to draw the upper or proximal segment of the ureter into the lumen of the lower or distal portion. The two ends of the catgut loop are tied firmly together, and one or two fine sutures inserted to fix together the fibrous and muscular coats of the ureter at the margin of the lateral aperture. The peritoneum is then replaced and sutured (in the trans-peritoneal operations), and the operation completed in the usual manner.

When lateral anastomosis cannot be performed, on account of the small amount of ureter which is left after a part has been removed, the two ends must be joined together directly by sutures either by the transverse or the oblique method, according to the manner of section. Figs. 152 and 153 show the different stages of these proceedings.

Uretero-vesical anastomosis.—As has already been mentioned, this operation is indicated in cases of resection of the lower part of the ureter in which too little ureter is left for uretero-ureteral anastomosis, and in those patients in whom the lower segment of the ureter has been excised on account of malignant growths of the bladder extending to it, or when the lumen has been practically entirely obliterated by hard fibrous tissue.

The methods of joining together the open end of the ureter and the bladder wall are depicted in Figs. 154 and 155.

OPERATIONS UPON THE URINARY BLADDER.

Puncture of the bladder.

—*Indications.*—Puncture of the bladder is indicated in cases of acute distension of the bladder, which cannot be relieved by the passage of a catheter, as in some forms of acute gonorrhœa; in some forms of enlargement of the prostate, when a catheter cannot be passed; and in cases of retention of urine dependent upon a stricture through which a catheter cannot be passed, and in which there is urgent need of relief of the distension. In gonorrhœal cases and in distension due to stricture, it is a temporary measure, and relieves the patient, whilst other measures, such as a hot bath, the administration of

- e. Aorta and common iliac arteries.

opium, passage of a catheter, etc., are being carried out.

Three routes are available for this procedure—(1) The suprapubic; (2) the rectal; (3) the perineal.

1. *The suprapubic method.*—It is often requisite in cases of enlarged prostate to keep the puncture opening permanent, and to pass inwards a trocar or catheter, which serves after-

FIG. 155.—Uretero-vesical anastomosis (Boldt's method). Diagrammatic section showing position of sutures.

- B. Sutures.
- C. Bladder well.

wards for the evacuation of urine.

When the puncture is intended as a temporary measure for the relief of an acute condition, the bladder should be punctured with the needle of an aspirator; and when it is intended to create a suprapubic urinary fistula, a trocar and cannula should be used.

(a) *Puncture with the needle of an aspirator.*—The bladder is steadied by an assistant placing one hand on each side and applying pressure in an inward direction. A point is then selected immediately above the pubes, and the needle of the aspirator forced inwards, until the point has entered the cavity of the bladder. The urine is allowed to flow out, the flow being aided by gentle, continuous pressure from above.

Care should be taken that the point of the needle passes well into the interior of the bladder; otherwise, as the bladder contracts and diminishes in size, the needle may slip out before all the contained urine has been drawn off.

This proceeding may be repeated at intervals, but it is not advisable to trust to this method of evacuation for any considerable length of time. When the wall of the bladder has once been punctured by this method, the urine should not be allowed to collect so as to considerably distend the organ, otherwise the point of puncture may leak, and urine pass into the adjacent tissues.

(b) *Puncture with a trocar.*—A point is selected in the hypogastric region immediately above the pubes, and then a trocar and cannula (Fig. 156) pushed into the bladder through the abdominal wall.

The trocar is withdrawn, leaving the cannula in position, and through the lumen of this a soft rubber catheter is passed into the bladder. The cannula may be fixed in position for a few hours and then removed, the catheter being left.

FIG. 156.—Trocar and cannula for suprapubic puncture of the bladder.

2. *The rectal method.*—A special curved trocar and cannula are needed for this operation. The patient is placed in the lithotomy position, and scrotum and penis held on one side.

The left index finger is inserted into the rectum, the prostate palpated, and the position of the trigone of the bladder determined. The trocar and cannula are then passed along the palmar aspect of the finger, and thrust upwards into the bladder through the antero-rectal wall immediately beyond the prostate. After the evacuation of urine, a catheter may be passed through the trocar and left in the bladder, whilst the latter is removed.

3. *The perineal method.*—Puncture of the bladder may be carried out through the perineum, a long straight trocar and cannula being entered at a point three-quarters of an inch in front of the anus, and thrust through the tissues of the perineum and prostate until the cavity of the bladder is reached. In order to guide the course of the trocar, the left forefinger is placed in the rectum.

Of these three methods, the rectal one is rarely practised; the special instrument and the troubles of a recto-vesical fistula, which it entails, render it inadvisable, nor is it easily performed.

Against the perineal method is the difficulty in some cases of reaching the bladder by this route, the fact that the opening is not at the most dependent point, and the chances of leakage into the pelvic cellular tissues, and attendant risks.

The suprapubic method of puncture of the bladder, however, is the one now almost universally practised.

Litholapaxy.—The term litholapaxy implies the removal of a stone from the urinary bladder at one sitting, by crushing it with an instrument called a "lithotrite" (which is introduced into the cavity of the bladder along the urethra), and immediately evacuating the fragments. The name "lithotrity" is often given to the operation, but this term ought to be limited to that form of operation in which the calculus is crushed at several sittings, and the fragments are allowed to be evacuated along with the stream of urine.

Removal of urinary calculi by crushing has replaced to a considerable extent the operation of lithotomy.

Indications.—Litholapaxy is indicated in all cases of calculus in the urinary bladder in which the stone can be readily grasped with the blades of the lithotrite, and is of a consistency which will allow crushing without danger of breaking the instrument.

In some cases of oxalate of lime calculi, the stone is so hard that it cannot be safely crushed with the lithotrite. When very large stones are present, it is only possible to remove them by lithotomy; but it may be said that, in the majority of cases in which the calculus can be grasped between the blades of the lithotrite, it will be possible to remove it by crushing, unless it is very hard and dense. Some surgeons have said that the operation ought not to be performed on young boys, but this statement appears to have been made without sufficient data, since it has been clearly shown that calculi can be easily and safely removed from the interior of the bladder of young male children by crushing.

Preparatory treatment.—The patient should be kept at rest for a few days previous to the operation, and fed on light, non-stimulating food. If a stricture of the urethra is present, it should be gradually dilated until a full-sized catheter can be easily introduced. The patient should be directed to retain his urine for an hour or more before the time of operation.

Special instruments.—Scalpel (to enlarge meatus if necessary), lithotrites of different sizes, evacuator and evacuating catheters, rubber catheter, and injection syringe (or a funnel and rubber tube).

Position.—The patient is placed in the dorsal position, near the right side of the operating table, with the buttocks slightly raised, and the legs extended and slightly separated; the surgeon stands on the right side, and the chief assistant opposite to him.

Operation.—The actual operation of litholapaxy can be divided into two stages, namely—(a) The introduction of the lithotrite, and crushing the stone into small fragments; and (b) removal of the fragments from the interior of the bladder with the evacuator.

(a) *Introduction of lithotrite and crushing of stone.*—A catheter is passed and the fluid contents of the bladder evacuated. With the injection syringe from 4 to 6 oz. of warm boracic solution are introduced, and then the patient is ready for the introduction of the lithotrite. The instrument is warmed and oiled, and then carefully passed along the urethra, care being taken not to allow the tip to catch against the anterior layer of the triangular ligament, this accident being obviated by allowing the instrument to pass along the urethral canal chiefly by its own weight, and not lifting the handle until the prostate has been reached. When the lithotrite has entered

the bladder, it is allowed to pass lightly over the trigone, so as to detect the locality of the stone. If the calculus can be felt on one side, the blades of the instrument are turned to the other side, the male blade is carefully separated from the female one, and then they are turned towards the stone and closed gradually, so as to fix the stone between the blades. If the stone is not felt at first, the blades of the lithotrite should be separated, the handle slightly raised so as to depress the blades, and then often the stone will fall in between them, in which case they are closed. If these manœuvres fail, the blades are opened and carefully turned from side to side, so as to explore the area of the trigone and the adjacent portions of the bladder; and if these measures are not successful, the handle should be depressed so as to raise the point of the instrument into the middle of the cavity of the bladder, and then turned round, and the floor examined with the blades in the reversed position. If these directions are systematically carried out, it will rarely happen that the surgeon fails to grasp the stone with the blades of the lithotrite. When the calculus has been fixed by the lithotrite, it is lifted towards the centre of the cavity of the bladder, and then the blades are screwed home and the calculus broken into fragments. These usually fall into the position where the calculus was first found, and hence it is an easy matter to repeat the procedure of seizing a portion of the calculus, lifting it to the centre of the cavity of the bladder, and then crushing it. This is repeated until the entire calculus has been reduced into small fragments, and then the blades are closed and the instrument withdrawn.

(b) *Removal of the fragments.*—An evacuating tube is next introduced, and the evacuator filled with a dilute solution of warm boracic acid, and connected with the tube. Pressure is

FIG. 157.—Litholapaxy.
Lithotrite.

now carefully and gradually applied to the bag of the evacuator, and 2 or 3 oz. of fluid are forced into the bladder.

Pressure is then relaxed, and the fluid is drawn back into the bag of the evacuator, carrying with it a number of the fragments. This procedure is repeated until all the fragments of the calculus have been removed. After each relaxation of pressure on the bag of the evacuator, a short time should be allowed to elapse before pressure is again exerted, so as to permit any fragments which have passed into the interior of

FIG. 158.—Bigelow's evacuator, for use in litholapaxy.

the tube to pass out if possible. If any of the pieces of the stone are too large to pass through the evacuating tube, either a larger tube must be introduced or the lithotrite must be again used, so as to reduce them to fragments of a smaller size. When there is difficulty in washing out the last few fragments, it will often be found to be advantageous to detach the evacuator and allow as much fluid as possible to pass out from the bladder, aiding the flow by suprapubic pressure, and then to again attach the evacuator and wash out as before.

After-treatment.—The patient is kept at rest for a few days

after the operation, and a catheter is passed to empty the bladder, if necessary. The occurrence of rigors and urethral fever is said to be more common after the operation of litholapaxy than after lithotomy, and by some surgeons a recurrence of the stone is thought to be more frequent.

Suprapubic cystotomy.—The operation of suprapubic cystotomy consists in making an aperture into the bladder through the hypogastric region of the abdomen.

Indications.—This variety of operation is indicated in the following conditions:—(a) The presence of calculi within the bladder which are too large or too hard to be easily crushed by the lithotrite, or when the local conditions of the bladder wall, or the general condition of the patient, are not favourable for the performance of a prolonged operation. (b) The presence of an encysted calculus of the bladder. (c) The removal of certain forms of intravesical tumour. (d) The removal from the interior of the bladder of foreign bodies which cannot readily and with safety be extracted through the urethra. (e) In some cases of ulceration of the walls of the bladder (tuberculous), so as to allow of direct treatment of the ulcerated areas. (f) In some cases of enlarged prostate.

FIG. 159.—Suprapubic cystotomy. Position of abdominal incision.

Special instruments.—Sharp hook, catheter, injection syringe or irrigation apparatus, rectal bag. When the operation is performed for stone, or the removal of a foreign body, lithotomy forceps and scoops will also be required; and when a tumour is being removed, curettes and cutting forceps are necessary.

Position.—The patient is placed in the dorsal inclined (“Trendelenberg”) position, the surgeon stands on the left side of the patient, and the chief assistant opposite to him.

Operation.—The operation may be divided into the following stages, namely—

(a) *Evacuation of the bladder and distension with aseptic fluid.*—When the patient has been anaesthetised, a catheter is introduced into the bladder, and all the fluid contents drawn off. An injection syringe or irrigation apparatus is filled with warm boracic acid solution, and usually about 8 to 12 oz. are injected, but this amount varies according to the condition of the bladder

walls, in many cases of cystitis not more than 3 or 4 oz. being introduced. Enough fluid should be injected into the bladder (if the condition of its wall will allow) to enable the surgeon to feel the fundus half way between the pubes and the umbilicus. The catheter is removed, and a bandage or piece of rubber tubing tied around the penis, so as to prevent the escape of the fluid.

(b) *Introduction and distension of rectal bag, if required.*—The rectal bag, after it has been oiled and rolled up in the form of a cone, is passed into the rectum by an assistant, and afterwards distended with about 10 oz. of warm fluid. It is better to introduce the rectal bag immediately before distending the bladder. In many cases it will be found better to distend the rectal bag after the cavity of the bladder has been opened.

The use of the rectal bag can be dispensed with in a considerable number of cases; it is of much use in patients with fat abdominal walls and a deep pelvis.

(c) *Parietal incision.*—A vertical incision from 2 to 3 in. in length is made, which commences about half an inch below the upper border of the pubic symphysis, and extends upwards towards the umbilicus. The abdominal wall is divided, if possible, through the interval between the two recti muscles; and in order to make this distinct, when the deep fascia has been cut through, an incision may be made transversely in the line of the pubic crests. The interval between the muscles is incised, and the margins of the wound held apart with retractors. The fascia transversalis is then divided for the entire length of the incision, care being taken not to notch the peritoneum in the upper part of the incision. The loose connective tissue which fills the prevesical space is now exposed, and often has a yellow appearance, owing to the presence of fat in its meshes. This tissue is carefully broken down either with the fingers or with dissecting forceps, and then the wall of the bladder becomes visible. This can be recognised by its tenseness and by its muscular fibres. The prevesical space *must not be opened up too extensively*, only such an area of the bladder being exposed as is sufficient to allow of the further procedures being carried out.

(d) *Opening of the bladder.*—A sharp hook is now taken, and its point pushed through the wall of the bladder at the upper extremity of the incision, never above the point of attachment of the urachus to the viscus, but always in front of and below it. The scalpel is forced through the wall of the bladder close to the point of entrance of the sharp hook, and an incision made downwards and towards the pubis, at first not more than 1 in. in length. When the incision in the wall of the bladder has been made, the fluid contents at once flow out and make the aperture apparent. Each margin of this

opening is seized with a pair of pressure forceps, which are not too tightly closed, and given to an assistant to hold. The finger is next passed into the interior of the bladder, and the presence and locality of a foreign body, calculus, or new growth determined. This investigation may be facilitated by the em-

ployment of a small electric lamp on a bent holder, which illuminates the interior of the bladder and allows the surgeon to see whatever pathological condition is being dealt with. A bent sound is also very useful in locating calculi or foreign bodies.

(e) *Performance of intravesical manipulations.*—The procedure during this stage of the operation depends upon the nature of

the affection from which the patient is suffering. When a calculus is present it is removed with a lithotomy scoop or forceps, preferably with the latter, since less injury to the adjacent tissues is likely to follow the use of forceps than when either a scoop or the fingers of the surgeon are used. At this stage of the operation some surgeons advise that the rectal bag should be dilated, so as to lift the bladder further into the parietal wound. Usually little difficulty will be experienced in removing calculi from the bladder after the cavity of the viscus has been opened. In old people, however, in whom the calculus is very large, and the walls of the bladder have undergone considerable thickening, difficulty may be met with in extracting the stone. Much help is often afforded by an assistant passing his fingers into the rectum and manipulating the stone from below. In all cases great care must be taken not to make a larger incision in the bladder wall than is necessary, or to cause any bruising or

FIG. 161.—Suprapubic cystotomy. Lithotomy forceps.

laceration of the margins of the incision or the parts of the wall of the bladder which lie in contact with the stone. During the removal of a foreign body, the exact form and size should be ascertained before attempting its extraction, so as to avoid further damage if the body happens to be a sharp one. Usually a foreign body can be readily extracted with the fingers or a fine pair of long-bladed forceps. When the bladder is the seat of an intravesical growth, this is removed either with a curette, a sharp spoon, by twisting with a pair of pressure forceps, or by division of the pedicle with the wire of an electric cautery. In epithelioma of the wall of the bladder, it is usually necessary to resect a portion of the wall of the viscus. Portions of the prostate and even the entire gland may be removed by the suprapubic route, in cases of chronic enlargement of the gland, dependent upon the formation of fibromyomata.

(f) *Closure of wound in bladder and parietes.*—The question as to whether the *vesical* wound ought to be sutured or not, depends upon the age of the patient and the condition of the

bladder walls at the time of the operation. When the muscular tissue of the bladder wall is healthy and possesses its normal contractility, and the mucous membrane is not the seat of ulceration or an inflammatory process, the wound ought to be closed by suture. This may be carried out in the following manner:—A blunt hook is placed in each angle of the incision, and given to an assistant to hold and exert slight traction during the insertion of the sutures; the mucous membrane is approximated by the insertion of a continuous suture of fine chromicised catgut; the cut surfaces of the muscular coat are fixed in apposition by the insertion of a row of fine sutures of silk or chromicised catgut, the sutures being about a quarter of an inch apart; and, finally, the superficial parts of the wound in the muscular coat are further closed by a row of sutures, introduced according to Lembert's method, and alternating in position with those which have been used to close the deeper part of the bladder wound. The parietal incision is now closed in the usual manner, with the exception that about half an inch at the lower angle is left open and a fine drainage tube passed down to the region of the wound in the bladder, so as to allow the escape of urine and any exudation which may occur if the suturing has not been perfect, or the wound does not heal by primary union. When the muscular coats of the bladder are thickened owing to chronic inflammation, or the muscular tissue has lost to a considerable extent its power of contractility, and the mucous membrane is the seat of inflammation (cystitis), or there are ulcerations in the interior of the organ, then suturing of the wound should not be adopted. In all cases of this kind the wound should be left open, a drainage tube inserted, and the area of the operation kept as aseptic as possible. It will usually be found advisable to fix the margins of the incision in the bladder to those of the parietal wound by the insertion of a few points of suture, and if the external wound is large the upper part may also be closed.

After-treatment.—When the wound has been closed, a soft rubber catheter should be passed into the bladder through the urethra and kept there for a few days, so as to allow the escape of urine as it is secreted, and prevent distension of the viscus, which might separate the margins of the wound and allow the urine to escape and so delay healing. When the wound is left open, a catheter or soft rubber drainage tube is passed into the interior of the bladder through the external wound, and a strip of absorbent gauze placed in its lumen, so as to facilitate the escape of urine and prevent accumulation within the bladder. The area of the operation must be kept as clean and aseptic as possible.

Lateral lithotomy or cystotomy.—In the operation of lateral lithotomy an oblique incision is made in the perineum, and deepened until the interior of the bladder is reached. It is performed for the extraction of vesical calculi and the removal of foreign bodies from the interior of the male bladder, and also in certain cases of chronic cystitis when it is wished to drain the bladder. The operation, however, has been superseded to a great extent by the suprapubic variety, and the increasing practice of litholapaxy.

Special instruments.—Sound, lithotomy knife, curved lithotomy staff with a left lateral groove, lithotomy forceps and scoop, and perineal drainage tube.

Position.—The patient is placed in the dorsal position at first while the staff is being passed and the presence of the stone is being confirmed, and then he is put in the lithotomy position for the remainder of the operation. The surgeon sits opposite the perineum, and an assistant stands on each side.

Operation.—The operation may be subdivided into three stages, namely—

(a) *Passage of staff.*—While the patient lies in the dorsal position, the surgeon passes a sound and confirms the presence of the calculus, and then passes the grooved staff into the bladder, which should also be made to strike the stone. The patient is next placed in the perineal position, the buttocks projecting slightly over the end of the table, whilst the surgeon seats himself directly opposite the perineum. The scrotum is drawn upwards, and the assistant directed to depress the handle of the staff so as to lift the membranous portion of the

urethra towards the surface of the perineum.

(b) *Perineal incision.*—A point is selected $1\frac{1}{4}$ in. in front of the anterior margin of the anus and immediately to the left of the median raphe, and a second one-third of the distance from the left

FIG. 162. — Lateral lithotomy. Staff with left lateral groove.

ischial tuberosity to the lateral margin of the anus, and then the lithotomy knife is taken and pushed inwards at the first point, until the staff is reached; it is next lateralised, *i.e.*, its edge directed towards the ischial tuberosity, and made to cut outwards to the second point in the ischio-rectal fossa. The tissues are divided by a kind of sawing movement. The incision made in this manner measures from 2 to 3 in. in length. The assistant now raises the handle of the staff until it is almost vertical, and at the same time lifts it up against the subpubic arch. The surgeon again introduces the knife, the point being placed in the groove of the staff, and the blade lateralised, and pushes it forwards into the interior of the bladder. The point of the knife must not be allowed to leave the groove in the staff as it is pushed into the bladder, otherwise difficulties may be met with. The forefinger of the left hand is placed on the back of the knife, and follows it into the interior of the bladder, the incision in the neck of the bladder and prostate being made large enough for the finger to pass in easily. The moment when the knife has entered the bladder is recognised, owing to a diminution of the resistance to the cutting edge of the knife, and also a gush of fluid from the interior of the bladder. When the finger is within the bladder, the knife and then the staff are withdrawn, and the calculus felt for.

(c) *Finding and extraction of stone or foreign body.*—When its position has been made out, the lithotomy forceps are passed into the interior of the bladder along the palmar surface of the finger, and the stone seized with the blades and extracted. If possible the long axis of the stone should be grasped with the forceps, so as to avoid unnecessary laceration of the tissues of the perineum during its extraction. In some cases a scoop will be found more useful than forceps, but usually the calculus can be extracted best and

FIG. 163.—Lateral lithotomy. Position of patient and line of perineal incision.

most easily with the forceps. The forefinger can often manipulate the stone between the blades of the forceps, and make the long diameter of the calculus correspond to the forceps. Before concluding the operation, the interior of the bladder should be examined for other calculi.

FIG. 164.—Special form of knife for use in lateral lithotomy.

When all calculi have been removed, the interior of the bladder is irrigated with an antiseptic solution, and a perineal drainage tube placed in the bladder, and the wound packed with tampons of aseptic gauze around the tube.

The chief difficulties which may be met with during the performance of the operation of lateral lithotomy are inability to find the bladder, injury to the artery to the bulb, or to the internal pudic artery, or injury to the rectum. The inability to find the bladder is generally due either to the fact that the staff is in a false passage, or more commonly to the surgeon allowing the point of the knife to leave the groove in the staff before the cavity of the bladder has been reached; injury to the artery to the bulb is caused by making the incision too far forward; and injury to the pudic artery by cutting too far outwards towards the ischial tuberosity; whilst damage to the rectum is caused either by cutting too far backwards, or not lateralising the knife sufficiently during the second stage of the operation.

Median lithotomy or cystotomy.—This is an operation which is very rarely performed. An incision is made in the middle line of the perineum a short distance in front of the anus, and deepened until the membranous portion of the urethra and the interior of the bladder has been reached.

Indications.—The presence of a small foreign body within the cavity of the bladder which cannot be removed through the urethra, the presence of a small vesical calculus which cannot be removed by litholapaxy, or the existence of a condition of the wall of the bladder which necessitates perineal drainage, as in some forms of cystitis, are by some surgeons said to be indications for the performance of median cystotomy.

Special instruments.—As for lateral lithotomy, with the exception that a curved staff with a median groove is taken instead of one with a lateral groove, and a long straight bistoury in place of the scalpel.

Position.—The positions of patient, surgeon, and assistant are similar to those recommended for the lateral operation.

Operation.—The staff with a median groove is passed along the urethra until the extremity is within the bladder, the handle is depressed towards the umbilicus, and held in this position by an assistant.

The surgeon passes his left forefinger into the rectum and steadies the staff as it lies in the membranous part of the urethra. The presence of the finger in the rectum enables the surgeon to avoid wounding this structure.

A long straight-bladed and sharp-pointed bistoury is taken and pushed into the tissues of the perineum, the point entering half an inch in front of the anterior margin of the anus. The cutting edge of the knife is turned towards the rectum. The knife is pushed inwards until the point enters the groove in the staff, the staff being now hooked up underneath the pubic symphysis. When the knife has reached the groove in the staff, it is pushed a little further inwards in order to notch the prostate. The knife is now withdrawn, and as this is done the perineal tissues in front are divided for a distance of an inch or a little more, the aperture being made large enough to allow of the extraction of the calculus or the foreign body. In the case of a calculus, it is advisable to make a small incision through which a lithotrite can be introduced, and the stone, if large, broken up into several fragments before an attempt is made to extract it.

A probe-pointed director is next passed along the groove in the staff into the cavity of the bladder, and the staff withdrawn. The forefinger of the left hand is passed along the director into the vesical cavity, the director is withdrawn, and the lithotomy forceps introduced. The stone or foreign body is now extracted in the usual manner, care being taken to avoid laceration of the perineal tissues.

As a rule, no drainage of the perineum is required in cases of calculus or removal of a foreign body. In cases of cystitis, a perineal drainage tube is inserted and fixed in position.

Treatment of a rupture of the urinary bladder.—Ruptures of the bladder are of two kinds—intra-peritoneal, when the rent causes the establishment of a communication between the cavity of the bladder and that of the peritoneum; and extra-peritoneal,

when the solution of continuity in the bladder wall involves that portion which is not covered by peritoneum. An intra-peritoneal rupture of the bladder is situated on the posterior or postero-lateral aspects of the upper two-thirds of the viscus. An extra-peritoneal rupture of the bladder is usually situated on the lower part of the anterior aspect, or in the region of the neck, but it may involve any part of the organ which is not covered by peritoneum.

Indications.—All cases of rupture of the bladder in which the diagnosis has been established, and in which the condition of the patient will allow an operation to be performed.

It is important that an operation should be at once performed when the existence of a rupture has been diagnosed. This is especially the case in intra-peritoneal rupture.

Special instruments.—Blunt hook, sponge-holders, catheter, needles (fine curved), needle-holder (Lane's cleft palate needle-holder will be found to be most useful).

Position.—The patient is placed in the dorsal posture on the operation table, the surgeon stands on the left side of the patient, and the assistant on the opposite side.

Operation (*for intra-peritoneal rupture*).—The operation may be conveniently divided into three stages—(a) Abdominal incision, opening of the peritoneum and finding the rupture; (b) closure of the rupture; and (c) closure of the external wound.

(a) *Abdominal incision, opening peritoneum, and location of rupture.*—An incision is made, commencing immediately above the pubic eminence and extending upwards for 4 in. towards the umbilicus and in the middle line.

The various strata of the abdominal wall are divided, until the parietal peritoneum and the summit of the bladder are exposed. At this stage it occasionally happens that laceration and ecchymosis of the fundus of the bladder becomes visible; if this is so, the extent of the injury should be made out.

The peritoneum is incised, and usually much fluid, chiefly blood-stained urine, will escape. With sponges, all urine and other fluid is removed from the peritoneal cavity; and then the visible coils of intestine are pushed upwards and held out of the way by the insertion of one or two large flat aseptic Turkey sponges.

The retropubic region is now carefully examined, in order to find the situation of the rent. When this has been found, its size and extent are ascertained. The interior of the bladder should also be examined, with the finger passed into its interior through the rupture, and should also be sponged dry so as to

remove all blood clots which may be present. •A blunt hook is now placed in the upper angle of the rupture and given to an assistant to hold, in order to facilitate the introduction of the sutures.

(b) *Closure of rupture.*—Two tiers of sutures should be inserted for the closure of the rupture; the first consists of several points of catgut suture, which approximate the mucous coat only. A continuous suture may be used for the mucous membrane, but usually it is not so easy to introduce as the preceding one. If silk be used for the mucous membrane, there is a possibility that at a later period salts from the urine may be deposited upon it. If interrupted sutures are used, all should be inserted before any are tied. These should be placed one-sixth of an inch apart. When they have been introduced they are tied, the lowermost ones first, and their ends cut short.

The sutures of the second tier are of fine silk. Each suture is introduced after Lembert's method, and transfixes the serous and muscular coats of the bladder wall on each border of the rent. The insertion of these sutures is commenced at the lower angle of the rupture; they are placed at intervals of one-fourth of an inch, or even less if necessary, until the entire aperture has been closed. The sutures should extend a short distance above and below the limits of the rupture. All the sutures are inserted before any are tied, then they are tied and their ends cut short. In cases where the rupture extends towards the lower part of the posterior aspect of the bladder, it will be found convenient to introduce the first suture a short distance above the lower angle, and then to use this suture to lift up the lower part and facilitate the introduction of the lowest sutures. The bladder is now examined in order to ascertain if it is water-tight. Often this can be effected by passing the hand behind the bladder and pressing it forwards against the posterior aspect of the symphysis pubis, when, if urine has collected within the interior of the bladder, it will exude through any deficiency which may exist along the line of suturing. If the line of suture is perfect, the abdominal wound can be closed. When, however, a leakage manifests itself, one or more sutures are inserted at the weak spot. If there is no urine in the bladder at the completion of the suturing, an aseptic fluid (4 oz. of carmine-coloured aseptic fluid) is introduced per urethram, and the procedure recommended above repeated.

(c) *Closure of the external wound.*—The region of the rupture is sponged dry, the flat sponges which have been used to keep back the intestines are removed, and the entire exposed part of

the peritoneal cavity freed from blood or blood-stained urine. Care must be taken not to leave a collection of fluid behind at the bottom of the pelvis.

The parietal wound is then closed in the usual manner by the insertion of two or three tiers of sutures.

If there is peritonitis, or there has been much escape of urine into the peritoneal cavity, it will be advisable to leave open the lower angle of the wound and to pass a glass drainage tube to the bottom of the pelvis. This can be removed in most cases on the following day. It will allow the ready escape of any urine or fluid which has been left behind, or which may be secreted by the peritoneum.

An aseptic soft rubber catheter is passed into the bladder along the urethra and tied in position. Provision is made for the collection of the urine as it trickles away through this catheter as it is secreted. This precaution avoids the distension of the bladder with urine, and hence promotes the quick union of the sutured margins of the rupture. This catheter should be changed daily. It can be permanently removed at the end of a week or ten days. The strictest aseptic precautions must be observed in connection with the passage of the catheter, in order to avoid the occurrence of cystitis.

Operation (*for extra-peritoneal rupture*).—When the anterior aspect of the bladder has been exposed, through an incision similar to the above, the region of the neck and anterior aspect is carefully examined in order to locate the rupture. If this is situated in the exposed area, the interior of the viscus is sponged dry, and then the margins of the rupture are united in the manner described above. When no trace of rupture can be discovered on this aspect, the peritoneum may be incised for a short distance and the peritoneal aspect of the organ laid bare. If no sign of rupture becomes visible, the opening in the peritoneum is closed.

When the symptoms point to unmistakable rupture, and the rent has not become visible by the previous procedure—a condition which very rarely occurs—an incision should be made in the anterior aspect of the bladder, as in the manner described in suprapubic cystotomy, and through this opening the base of the bladder and the region of the prostate are examined. If a rupture is discovered, the margins are sponged dry and then united by a series of catgut sutures, introduced from the interior of the bladder. The wound in the anterior aspect of the bladder is closed in the ordinary manner. The abdominal wound is only partially closed in cases of extra-peritoneal rupture, the lower

part being left open, and through this a drainage tube is passed down towards the region of the rupture. This will allow the escape of the extravasated urine.

The further treatment of extra-peritoneal rupture is similar to that described in connection with the other form of rupture.

OPERATIONS UPON THE URETHRA.

External urethrotomy (Wheelhouse's operation).—In this operation the urethral canal is opened from the perineum by a median incision.

Indications.—The performance of this operation is indicated in cases of retention of urine dependent upon an impermeable stricture in the proximal portion of the urethra, and in traumatic rupture of the urethra.

Special instruments.—Clover's crutch, Wheelhouse's staff, long straight bistoury, probe-pointed gorget (Teale's), probe-pointed director, fine probes, silver catheters, "railroad" catheter.

Position.—The patient is placed in the lithotomy position, the legs being held apart by a Clover's crutch. The surgeon seats himself opposite the perineum, and his assistant stands on his left hand.

Operation.—Wheelhouse's staff is passed along the urethra until the extremity comes into contact with the stricture, the groove is turned towards the operator, and it is held in this position by an assistant.

An incision is made in the median raphé of the perineum, about $1\frac{1}{2}$ or 2 in. long, and not extending nearer the anus than the anterior margin of the external sphincter. This is deepened by cutting the fasciæ and the accelerator urinae muscle, until the groove in the staff is reached. The urethra is then opened in front of the stricture for about 1 in., but care should be taken that the section of the urethral wall does not extend beyond a point one-third of an inch from the stricture. The margins of the urethral incision are picked up with forceps, and a silk ligature passed through each side. These ligatures are left long and not tied, the ends being given to assistants to hold;

FIG. 165.—Wheelhouse's staff for external urethrotomy.

FIG. 166.—External urethrotomy (Wheelhouse's operation). Position of patient and (a) line of external incision.

be made on the bladder from the suprapubic region, in the hope that urine will be expressed, or, failing this, the finger of an assistant should be passed into the rectum, and pressure exerted upon the vesiculæ seminales, and seminal fluid forced onwards.

The aperture having been found by one of these methods, the probe-pointed director is passed through it into the urethra beyond the stricture and thence into the bladder. The groove of the director is turned towards the surgeon, and the stricture divided with a fine scalpel or a sharp-pointed bistoury. When the stricture has been divided, the groove in the director is turned away from the surgeon, and the probe-pointed gorget passed along this groove until the cavity of the bladder has been reached, which is known by a sudden escape of urine.

The staff is removed, and the part of the urethra in front of the incision examined for fibrous bands, and if any are found, they are divided. Next a full-sized "railroad"

they serve as retractors. Next, the staff is slightly withdrawn and half turned round, so that the hook on the tip is brought into the upper angle of the wound. By these means the incision in the urethra is held open at three points—laterally and at the upper extremity. The probe-pointed director is now taken and the proximal portion of the urethral canal sought for. Often this can easily be seen, but occasionally considerable difficulty is experienced in finding it. In such cases pressure may

FIG. 167.—Teale's probe-pointed gorget.

gum-elastic catheter (No. 12) is passed along the urethra from the meatus to the perineal incision, and then along the gorget until it passes into the bladder. The gorget is withdrawn, and the catheter tied in the bladder.

The temporary ligatures are removed from the margins of the incisions in the urethral canal, and the wound packed with strips of aseptic gauze, and a perineal bandage applied.

A tube should be fastened to the end of the catheter to convey the urine to a receptacle underneath the bed.

After-treatment.—The catheter should be left in for from four days to a week, and the perineal wound dressed daily. In most cases it is wise to change the catheter on the third or fourth day. When the catheter is changed, a long catgut is passed through it into the bladder, and over this the old one is drawn out and the other introduced. Afterwards the catheter is not retained in position, but a full-sized one is passed each day until the external wound has closed.

A catheter ought to be passed regularly for several months, or even longer, after the perineal wound has healed, so as to prevent the recurrence of the stricture.

Internal urethrotomy.—The essential feature in this operation is that the constricted portion of the urethra is cut from within the lumen of the urethral canal, by an instrument which is passed downwards along the urethra until the constricted portion is reached. Two methods are adopted for dividing the stricture,—thus, one in which the cut is made from behind the stricture forwards, and the other by cutting from without inwards. In order to perform the former operation, it is necessary that the strictured portion of the urethra be dilated sufficiently to enable the operator to pass an instrument with a diameter equal to a No. 4 catheter, whilst in the latter it is only necessary that it should be wide enough to permit the passage of a filiform bougie (No. 2).

Indications.—Only few cases of stricture can be said to be

FIG. 168.—Railroad catheter.

specially suitable for the performance of the internal operation. These are—(a) Cases of annular or ring-like strictures, in

which only a small portion of the length of the urethral canal is affected, and which are not amenable to dilatation, or when dilated quickly return, and also those in which rigors constantly follow the use of a dilating bougie. (b) Strictures located in the penile portion of the urethra which are not amenable to dilatation. (c) Some forms of traumatic stricture which cannot be dilated satisfactorily, and in which it is not advisable to perform an external operation.

By cutting from within outwards.—The instrument used for this operation is straight and has a small bulbous enlargement at the distal extremity, in which is concealed a small sharp knife (Fig. 169, a).

The instrument is passed along the urethra down to the situation of the stricture, and then manipulated through it until the bulbous extremity is in the urethra beyond the strictured portion. The region of the stricture is steadied with the hand, the knife protruded as in Fig. 169, b,

FIG. 169.—Thompson's modification of Civiale's urethrotome.

- a. Bulbous extremity with knife ensheathed.
b. Bulbous extremity with knife protruded.

and then the entire instrument is drawn outwards, the knife cutting through the fibrous tissue as it is withdrawn. When the

knife has been drawn beyond the stricture, the blade is ensheathed again, so as to avoid injury to the urethra on the distal side of the stricture. The cutting edge of the knife is generally made to look towards the roof of the urethra. When the urethrotome has been withdrawn, a full-sized sound or bougie is passed through the stricture to ascertain if any part remains undivided. If this is so, the urethrotome is again introduced and withdrawn as before.

By cutting from without inwards.—A urethrotome of a pattern similar to that shown in Fig. 170 is required for this operation. The urethrotome consists of a split steel sound with a shield in the position (Fig. 170, *b*), containing a small sharp, triangular knife, which can be protruded at will, and a filiform bougie attached to the distal extremity. When performing the operation, the filiform bougie is passed along the urethra through the stricture into the bladder. The urethrotome is then passed along the urethra until the triangular or wedge-shaped shield comes into contact with the distal extremity of the stricture. The apex of the shield is insinuated into the first part of the stricture by gentle manipulation, and when it has been passed as far as it will go, the knife is protruded from the shield and made to incise the constricting fibrous tissue in the wall of the urethra which impedes its progress. The knife is withdrawn into the sheath, and then by manipulation of the urethrotome the wedge-shaped prominence is made to pass further along the tract of the urethra until its progress becomes arrested. Then the knife is protruded and the constricting tissue divided as before. It is not necessary to divide the urethral wall

always in the same line, as the instrument can be turned and

FIG. 170.—Urethrotome for cutting from without inwards.

- a.* Filiform bougie.
- b.* Shield.
- c.* Knife protruded.

small cuts made in the ventral, dorsal, or lateral walls of the urethra. When the stricture has been completely divided, the knife is drawn into the shield and the urethrotome taken out. A full-sized bougie or sound is then passed through the stricture, as in the previous operation.

After-treatment.—A full-sized bougie is passed into the bladder and tied in. It remains there for one or two days, and is then removed. Afterwards the size of the urethral passage is maintained by passing a full-sized bougie at intervals. It is necessary to keep the patient at rest in bed for eight to twelve days after the operation.

Hæmorrhage may occur after the operation, in which case it is arrested and controlled by applying a pad to the perineum and exerting pressure on the surface of the intra-urethral bougie. Patients who are suffering from urethritis ought not to be submitted to internal urethrotomy, on account of the liability of occurrence of rigors, perineal abscesses, extravasation of urine, and septicæmia.

Treatment of rupture of the urethra.—An operation is requisite in all cases in which the urethra is torn across or completely ruptured, and also in cases of partial rupture in which either a catheter cannot be passed into the bladder or there is considerable hæmorrhage and bruising of the tissues of the perineum.

Special instruments.—Straight sound, probe-pointed director, Teale's gorget, full-sized catheters.

Position.—As in external urethrotomy.

Operation.—A grooved straight staff is passed along the urethra as far as it will readily go, and the extremity made to protrude towards the perineum. (The seat of the rupture in the great majority of cases is immediately in front of or at the perineal aspect of the triangular ligament.) With a scalpel the tissues are divided in the middle line of the perineum, until the groove of the staff is exposed. The urethra is then divided on the ventral aspect along this groove until the position of the rupture becomes apparent. The external wound is generally $1\frac{1}{2}$ to 2 in. long, and terminates half an inch in front of the anus. When this has been done, all extravasated blood and clots are, as far as possible, turned out of the wound, and any bleeding vessels picked up with pressure forceps and ligatured. The ends of the ruptured urethra are now sought for. The distal is readily found by examining the end of the staff which passes through it. The proximal end can often be seen as a small bleeding prominence or blood clot. Careful

sponging and the employment of a good light are essential requisites in the search for the end of the torn urethra, especially when the injury is near the triangular ligament. When found, a black catheter should be passed through the meatus into the wound, and thence along the proximal part of the urethra into the bladder. Next, if possible, the margins of the torn tube are brought into apposition and fixed by careful suturing with fine silk sutures. Sometimes this is not possible, owing to the difficulty of bringing the torn margins into apposition. The external wound is only partially closed, a sufficient aperture being left for the exit of blood, urine, or any other material. When no catheter can be passed into the bladder, the external perineal wound is left entirely open, so as to allow a free exit for the urine. In some of these latter cases it may be necessary, for the first few days, in order to evacuate the urine from a distended bladder, to aspirate this viscus above the pubes. This, however, should not be done until after the failure of other methods. In the favourable cases in which it is possible to unite the margins of the torn urethra, it must be remembered that it is necessary to continue catheterisation for a long period, otherwise a severe form of traumatic stricture will result.

CHAPTER IX.

OPERATIONS UPON THE MALE GENITAL ORGANS.

OPERATIONS UPON THE PENIS—

Circumcision.

Amputation of the penis :

(a) Partial.

(b) Complete.

OPERATIONS UPON THE TESTICLE—

Castration.

Radical cure of hydrocele.

OPERATIONS UPON THE SPERMATIC CORD—

Varicocele.

Vasectomy.

OPERATIONS UPON THE PENIS.

Circumcision.—Circumcision, or removal of the male prepuce, is necessary in many cases of phimosis ; to facilitate the treatment of certain venereal conditions ; and it is often advisable in patients who have a congenitally long prepuce, which allows the preputial secretion to collect underneath it and become a source of irritation.

Position.—The patient is anaesthetised, placed in the dorsal posture, and the genital region well exposed. The surgeon may stand on either side of the patient, and his assistant opposite to him.

Operation.—The prepuce is drawn slightly forward, and then seized with a pair of dressing forceps immediately in front of the corona glandis. The blades are held in a sloping direction, so that more prepuce is beyond the forceps on the dorsal aspect than on the ventral. The blades are closed, the glans penis slipping backwards, and the part of the prepuce which is distal to the forceps removed by cutting it away with the scalpel.

The mucous surface of the prepuce is now completely

separated from the glans by peeling it backwards with the finger or a probe, and cut away with scissors to within a quarter of an inch of the corona glandis. The skin of the prepuce is next trimmed away with scissors as far as the frenum, care being taken to leave the skin pointed immediately underneath the attachment of the frenum. All bleeding is arrested by ligature, and the free margin of the skin united to that of the mucous membrane just beyond the corona glandis, by the insertion of a series of interrupted sutures of fine silk or catgut. The organ is then washed with an aseptic solution, thoroughly dried, and then the line of incision is covered with a thin strip of gauze and painted with a solution of collodion and iodoform. In children, fine catgut sutures should always be used.

At the expiration of five days to a week, this dressing can be taken off and the stitches removed. A lint dressing with a small quantity of boracic ointment is then applied, and replaced daily until the wound has completely healed.

Amputation of the penis.—Amputation of the penis may be either partial or complete; in the former case, a portion of the dependent organ is removed, and in the latter the entire structure including the crura is taken away.

Indications for operation.—The operation is rendered necessary in certain cases of epithelioma of the penis, where it is possible to remove the entire diseased tissue, and occasionally in gangrene of the organ, induced by constriction of rings and other bodies.

Partial amputation of the penis.—The dependent portion of the penis may be amputated at any point between the posterior portion of the glans and the junction of the organ with the scrotum.

Many methods of removing a portion of the penis have been adopted by different surgeons, but one which is easy to perform, and, in addition, gives excellent results, is known as the "flap" operation. This is the one which is now described.

FIG. 171.—Circumcision. Penis showing phimosis.

- a. Line of application of dressing forceps when prepuce has been drawn forward.
- b. Extremity of glans penis.
- c. Aperture of prepuce.

Special instruments.—Long narrow-bladed knife, and fine-toothed forceps, No. 12 gum-elastic catheter with metal stylet, sharp hooks, elastic rubber tube.

Position.—The patient lies on his back near the right side of the operation table, with his thighs slightly separated; the operator stands on the right side, and the assistant opposite to him.

Operation.—An elastic ligature is placed around the root of the penis, so as to avoid hæmorrhage. The plane of the penis at which it is wished to effect the separation is decided upon, and then a dorsal skin flap is made, equal in length and breadth to half the circumference of the organ at the line of section, and dissected back. A ventral flap is then fashioned in a similar manner, but only a quarter of the length of the dorsal, and

FIG. 172.—Circumcision. Appearance of penis when prepuce has been removed, and margins of incision united with sutures.

a. From lateral aspect.

b. From ventral aspect, showing method of suturing at frenum.

dissected back as far as the line of section. The gum-elastic catheter with stylet is passed along the urethra, and then the long narrow-bladed scalpel made to transfix the body of the penis between the corpus spongiosum and the corpora cavernosa, immediately anterior to the bases of the skin flaps. The catheter is removed, and the corpus spongiosum with the urethra divided about half an inch in front of the posterior part of the incision. The corpora cavernosa are next divided on a level with the bases of the skin flaps, and all bleeding vessels tied. The arteries which require ligature are—the two dorsal arteries, on the dorsal surface between the two corpora cavernosa; the arteries to the corpora cavernosa in the substance of these structures; and a branch of the artery to the bulb in the walls of the bulbous part of the urethra. The elastic

FIG. 173.—Amputation of part of penis.

- a.* Lines of skin incisions in formation of flaps.
b. Appearance of stump when part to be amputated has been removed.

ligature placed around the base of the penis is slightly relaxed, so as to make evident the position of these blood vessels. Any other bleeding points are ligatured, and then a small vertical incision, half an inch in length, is made in the middle of the dorsal flap. The projecting portion of the corpus spongiosum is brought through this aperture, split vertically for a short distance, and the two pieces sutured to the margins of the aperture by curved needles threaded with fine silk. The edges of the dorsal and ventral flaps are brought in apposition, and fixed by the insertion of a row of silk sutures. The operation is now completed by the application of a collodion dressing to the lines of suture. The retention of a catheter is not necessary after the performance of this form of operation. Contraction of the new meatus is said not to occur

FIG. 174.—Amputation of part of penis. Operation completed.

so commonly after this method of amputation as after some of the other methods.

Complete amputation of the penis.—This operation comprises the removal of the entire penis together with the crura. It has been called Thiersch's, and also Gould's operation.

Special instruments.—These are the same as those required for the previous operation, with the addition of a rugine or a periosteal elevator.

Position.—The patient is placed in the lithotomy position, the buttocks projecting slightly over the end of the operation table; the operator stands between the legs of the patient, and the assistant on his left side.

Operation.—The operation may be divided into the following stages, namely—(a) Skin incision; (b) splitting the scrotum; (c) division and separation of the bulbous portion of the corpus spongiosum; (d) removal of the remaining portion of the penis including the crura; (e) fixation of the proximal portion of the corpus spongiosum to the posterior angle of the incision, and closure of the remaining part of the external wound.

(a) *Skin incision.*—An incision is made with the scalpel, which commences on the pubic eminence immediately above the dorsal aspect of the root of the penis, extends round the penis to its ventral aspect, and then backwards along the median raphe of the scrotum as far as the anterior part of the perineum.

This incision is racket-shaped, and it divides the skin and fasciæ.

(b) *Splitting the scrotum.*—With the fingers and the scalpel the scrotum is divided into two lateral halves, until the ventral aspect of the corpus spongiosum is reached. The gum-elastic catheter with stylet is next passed into the urethra as far as the anterior layer of the triangular ligament.

(c) *Division of the corpus spongiosum, and separation of the proximal portion.*—A long narrow-bladed scalpel is inserted transversely between the corpus spongiosum and the corpora cavernosa, a little in front of the bulb. The catheter is withdrawn, and the knife made to cut outwards and divide the corpus spongiosum not quite half an inch in front of the bulb, a point which is beyond the termination of the ducts of Cowper's glands. When this has been done, the proximal portion of the corpus spongiosum is seized with toothed forceps and dissected free from the crura as far back as the triangular ligament.

(d) *Separation and removal of the remaining portion of the penis.*—The surgeon then grasps the body of the penis with the left hand, and, taking the scalpel in the right hand, he divides

the suspensory ligament and other fibrous tissues which fix the organ to the adjacent structures. When the attachments of the crura to the ischio-pubic rami have been exposed, the scalpel is laid aside and the rugine taken, and with it the crura are separated from their bony attachments, and the organ removed. Four arteries require ligature—the two dorsal arteries of the penis, which will be found immediately underneath the pubic arch, and the arteries to the corpus cavernosa, which come through the triangular ligament close to the attachments of the crura to the bone. These vessels are secured and ligatured, together with any other bleeding points which may become apparent.

(e) *Fixation of the proximal portion of the corpus spongiosum, and closure of the external wound.*—The remaining piece of the corpus spongiosum is seized with toothed forceps and slit for half an inch along the dorsal and ventral aspects, and then the flaps so made are united to the margins of the posterior part of the incision by the insertion of fine silk sutures. The anterior part of the incision is well sponged out, the two halves of the scrotum brought together, and the margins closely united with silk sutures, a drainage tube being passed into the deeper part of the wound, if it is thought to be requisite, on account of the oozing of blood which usually goes on for a short time after the operation. It is not necessary to retain a catheter in the urethra.

* OPERATIONS UPON THE TESTICLE.

Castration.—Removal of both testicles is called castration, but either one or both organs may be removed, according to the nature of the affection from which the patient is suffering.

Indications for operation.—Removal of the testis is indicated in certain cases of malignant disease of the organ, in some forms of tuberculous and syphilitic affection, and often in cases of “fungus testis.” Removal of both testes has recently been advocated as a method of treatment for chronic enlargement of the prostate, but the advisability of this procedure has not yet been definitely decided.

Special instruments.—Clamp forceps (for holding the stump).

Position.—The patient lies upon his back with the legs extended and the thighs slightly separated; the surgeon stands on that side of the patient which is to be operated upon, and the assistant on the opposite side.

Operation.—An incision is made which commences above,

a short distance below the external abdominal ring of the affected side, and extends downwards on the lateral aspect of the scrotum to its inferior border. This is made to extend through the tissues of the scrotum until the spermatic cord and the testis with the tunica vaginalis are fully exposed. The spermatic cord is clearly defined, and a clamp placed upon its coverings on each side immediately below the external ring; an aneurysm needle is passed through the cord below the level of the clamps, and a double ligature inserted. Each half of the cord is tied separately, and one ligature is made to surround the entire structure. The cord is then divided a short distance below the application of the ligature, and the distal portion of the spermatic cord and the testis and its tunica vaginalis removed. All bleeding points are ligatured, and then the clamps on the spermatic cord are removed, and if any of the arteries bleed they are picked up with artery forceps and tied separately. When all bleeding has been arrested, the stump is pushed into the inguinal canal, and the external wound is closed by the insertion of a series of interrupted sutures. Some surgeons advise that the vessels of the spermatic cord should be tied separately, each one being picked up with artery forceps; this is, however, not usually necessary.

FIG. 175.—Removal of testis.
External incision.

In the latter method a circular ligature is not placed around the entire cord. The method of transfixion of the spermatic cord, however, is the easier and safer one.

Radical cure of hydrocele.—The operation for the radical cure of a hydrocele involves the removal by dissection of the parietal layer of the tunica vaginalis testis.

Indications.—An attempt at a radical cure of a hydrocele ought to be made in all cases in which the sac wall is very thick, and also in those cases which have resisted milder methods of treatment, such as tapping, or tapping and injection.

Position.—The patient is placed in the dorsal position, with the thighs slightly separated, and a sandbag of suitable size placed underneath the scrotum in order to raise it; the surgeon stands on the affected side, and his assistant opposite.

Operation.—The scrotum being made tense by the assistant, an incision is made on the lateral aspect of the affected side. This incision extends the entire length of the swelling caused

by the hydrocele. The skin, dartos, and fasciæ are divided, until the surface of the hydrocele is laid bare. All bleeding from the scrotal vessels is arrested, and then an incision, sufficiently large to admit the forefinger, is made into the sac of the hydrocele, care being taken to avoid the region of the testis. As the contained fluid exudes, the forefinger is introduced into the interior of the sac, and its extent and the exact position of the testis defined. When this has been done, the opening in the sac is enlarged with scissors until the entire length has been incised. Next, the sac walls are seized with pressure forceps, and the parietal portion of the sac separated from its connections with the scrotal tissues. This having been done, the parietal portion is removed by cutting it away with scissors a short distance beyond the junction of the visceral and parietal layers. All bleeding is arrested, and the external wound closed by the insertion of sutures.

Some surgeons advise that the margins of the aperture in the tunica vaginalis testis should be united to those of the scrotal incision, but this is not necessary, and it tends to delay healing of the wound.

OPERATIONS UPON THE SPERMATIC CORD.

Varicocele.—In this affection the veins of the spermatic cord are abnormally enlarged. The spermatic veins form a plexus, which is called the pampiniform plexus, and this plexiform arrangement extends from the upper border of the testicle to the internal abdominal ring, where the veins join together and form either the spermatic vein or the venæ comites of the spermatic artery. The veins lie in front of the vas deferens and the spermatic artery.

Two distinct operations are practised for the cure of a varicose condition of the veins of the spermatic cord. In the first operation the veins are exposed through an open incision, and in the other they are ligatured subcutaneously.

Special instruments.—As for ligature of an artery.

(a) *Open method.*—*Position.*—The patient is placed in the dorsal position, with a pillow between the thighs. The surgeon stands on the affected side and the assistant opposite to him.

Operation.—An incision about 2 in. long is made in the long axis of the scrotum, commencing above over the external abdominal ring and just internal to the pubic spine (Fig. 176). The skin and fasciæ are divided and the spermatic cord laid bare. The dilated veins are next separated from the surrounding struc-

tures for a distance of about $1\frac{1}{2}$ to 2 in. or more, according to the length of the scrotum. When this has been done, the vas deferens is held away by the assistant, and two ligatures passed around the separated veins, one at the upper and the other at the lower part of the incision. These ligatures are tied, and the intervening portion of the veins removed. The ligatures are then tied together so as to fix the cut ends of the veins in approximation; the ends are cut short, and the external wound closed in the usual manner.

(b) *Subcutaneous method.*—*Position.*—As in the previous operation.

Special instruments.—A long round needle with a blunt point.

Operation.—The assistant grasps the affected half of the scrotum in such a manner that the veins are held between his fingers and thumbs, whilst the spermatic artery and the vas deferens slip behind out of the way. The surgeon with the left hand defines the exact position of the vas deferens, and then makes a very small incision with the scalpel through the skin. The needle is then entered in such a manner that it passes between the vas deferens and the spermatic veins, and emerges on the opposite part of the affected half of the scrotum, this being facilitated by making a small cut with the scalpel on to

FIG. 176.—Open operation for cure of varicocele.

a. Line of skin incision.

b. External abdominal ring.

the point of the needle. It is most convenient to make the needle enter posteriorly and emerge anteriorly. The needle, which is already threaded, is drawn right through the scrotum, carrying the ligature with it. The point is now made to enter the aperture of exit, to pass through the tissue of the scrotum superficial to the veins and underneath the skin, and then to emerge through the original aperture of entrance. The ligature is brought through with the needle, and then tied with an ordinary reef knot tightly enough to occlude all the included veins. The ends are cut short, and the knot made to pass into the scrotum through the aperture of entrance of the needle. Both apertures are painted with collodion and a dressing applied.

The open operation is advisable in all cases where the varicose veins are very numerous and large, but for slight cases the subcutaneous operation is better, since the patient need only rest for a few days.

Great care must be taken in this latter procedure to avoid inclusion of the vas deferens in the ligature.

Vasectomy.—The removal of a portion of the vas deferens constitutes this operation. Simple occlusion of the vas by ligature is sometimes adopted in its place with similar results.

Indications.—This operation is indicated in some cases of general enlargement of the prostate.

Operation.—The operation is conducted in a similar manner to the open operation for varicocele. When the constituents of the spermatic cord are exposed, the vas deferens is recognised by its definite cylindrical shape, pinkish-white colour and hardness. It is isolated, and either two ligatures applied and the intervening portion removed, or a single ligature simply tied. The wound is closed and dressed, as in the operation for varicocele.

CHAPTER X.

OPERATIONS UPON THE FEMALE GENITAL ORGANS.

OPERATIONS UPON THE VULVA.

1. **Removal of urethral caruncle.**—Small vascular growths of this nature may be removed either by the cautery or scissors. Their removal is sometimes attended with troublesome bleeding. Removal by the cautery, under anæsthesia, is the simplest method. The patient is placed in lithotomy position, and the urethral orifice exposed. The growth is then thoroughly burnt away by the cautery at a dull red heat, care being taken to destroy its base. Bleeding afterwards may be arrested by pressure; this sometimes occurs later when the slough separates.

The growth may also be dissected carefully away by scissors, after dilating the urethra and exposing the base of the tumour. Any bleeding is controlled by suture. The urethra is dilated by metal instruments similar to those used for the cervix uteri. Catheters may be necessary after either of these operations for a few days, but in most cases patients pass their water naturally.

2. **Imperforate hymen.**—In this condition a septum closes the vaginal orifice. It is really a vaginal atresia, and is independent of the hymen altogether.

Operation may be necessary for retained secretions, or for the deformity itself. The condition may be associated with hæmato-colpos and hæmatometra.

Operation.—The patient is placed in the lithotomy position, and the septum carefully incised. It is well to determine the position of the urethra, and avoid injuring either this or the rectum. The evacuated fluid is generally dark coloured, and very tenacious. It is better not to attempt to wash the sac out, as it easily becomes infected. The discharge may be allowed to drain into pads of aseptic gauze. It is very difficult in some cases to keep the opening permanently patent, even if the

patient wears mechanical appliances. In some cases removal of the uterus may be justifiable.

3. **Tumours of the vulva.**—These may involve either the labia or the clitoris, and include cysts of Bartholin's gland, papillomata, fibromata, lipomata, elephantiasis, and malignant disease.

The commonest tumours are cysts of Bartholin's gland or duct. They should be dissected away entire, if possible, or if incised, the cyst wall should be completely removed. If the cyst has suppurated, incision and drainage is all that is possible. If any vessels are divided, they should be ligatured; troublesome oozing may be stopped by deep sutures and closure of the wound. Cysts sometimes occur in the canal of Nück. Papillomata and fibromata are easily removed by incision around their base, the skin edges being afterwards brought together by sutures.

Sometimes large tumours of the labia or clitoris may occur, due to hypertrophy or true elephantiasis, resembling those occurring in the scrotum. They may necessitate removal. Large vessels may be divided in removing tumours of this nature, which should be secured as they are divided. If the clitoris is affected, this may need removal.

The most frequent form of malignant disease of the vulva is a squamous-celled carcinoma. It may occur on the labia or clitoris. The urethra is not commonly affected. Localised malignant growths may be removed by free incision beyond their limits. Bleeding should be arrested at once. If the inguinal glands are affected, they should be removed at the same time.

If the cautery is used for the removal of cancerous tumours, the wound is left to heal by granulation.

OPERATIONS ON THE FEMALE PERINEUM.

These are generally performed for rupture occurring during labour, or where the vulval orifice is very lax, as in prolapse of the uterus or vaginal walls.

All laceration of the perineum during labour should be at once sewn up, and even if the operation fails, the edges of the wound may be subsequently refreshed and re-stitched. Rupture of the perineum may be either *partial* or *complete*. In the latter case the rectum is involved. Central rupture of the perineum is very rare.

Very severe lacerations of the perineum may involve the recto-vaginal septum to a varying extent.

1. **Operation for partial rupture.**—Many operations have been invented for this condition, but the simplest is the flap-splitting method described below.

Special instruments.—Clover's crutch, Sims' or Auvard's speculum, scissors which should be sharp-pointed and angular.

Position.—The patient is placed in lithotomy position, the buttocks being allowed to project somewhat beyond the table. The surgeon sits opposite the perineum, and an assistant stands on either side of the patient's legs.

In operating on the perineum, the vagina should be swabbed out with an antiseptic, so that no discharge can subsequently foul the seat of operation.

This is an important matter. If there is a discharge from the cervix, this should be swabbed away, and 90 per cent. carbolic acid applied to the canal. A preliminary dilatation and curetting may be necessary in some cases before proceeding to the perineal operation.

Operation.—An incision is made with the knife or angular scissors, commencing at the posterior margin of the rupture, and extending forwards, as in Fig. 177. By this means a U-shaped flap is raised. The surgeon next seizes the lowest portion of the vaginal flap with

FIG. 177.—Rupture of perineum (partial). Line of first incision.

- f. Torn surface which has granulated.
- g. Anus.

a pair of Spencer Wells' forceps, and this is raised further by splitting the recto-vaginal septum. The dissection is continued to the limits of the U-shaped incision on either side. Care should be taken not to wound the rectum or button-hole the vaginal flap. If the vaginal flap be kept fairly thin, the large rectal veins will be avoided. When the right layer of separation between the vagina and rectum is reached, the further separation can be done by the fingers. Fig. 178 shows the vaginal flap well dissected up. It frequently happens that the vaginal flap is uselessly large, and it is a good plan to cut some away by a V-shaped incision, and then close the gap so made by a series of chromic gut or silk-worm gut sutures.

These are passed from the vaginal surface and tied, so that, when the gap is closed, the knots lie on the vaginal surface. This facilitates their removal, if necessary. Care should be taken to get perfect apposition of the edges, and thus prevent any septic discharges infecting the perineal wound. Some operators diminish the redundant vaginal flap, by doubling it up on itself by means of a continuous suture which starts at the apex of the flap, and so bringing the edges gradually together. This makes a sort of thick spur, which, when included in the lateral deep sutures, helps to strengthen the perineum.

Having dealt with the vaginal flap, all bleeding should be arrested and the deep lateral sutures introduced. A large curved or handled needle is entered on one side of the U-shaped incision close to the skin margins, pushed through the tissues in the floor of the wound, and then brought out at a similar spot on the opposite side. The sutures are generally put in from below upwards. Care should be taken not to puncture the rectum, or any large vessel. The other sutures are now passed, the upper ones taking in the structures of the vaginal flap, but not appearing on its vaginal surface. The method of introducing the sutures is shown in Fig. 178. The sutures are then tied, and the raw surfaces of the lozenge-shaped wound brought into exact apposition from behind forwards. Before doing so, the cavity should be cleansed from all clot. Any oozing stops as soon as the sutures are tied. The skin edges should be brought into exact apposition with a few superficial sutures.

The same care should be taken with the mucous surfaces, at the upper margin of the wound where it meets the apposed

- g.* Raw surface exposed by raising vaginal flap.

vaginal flap. This prevents the entrance of septic discharges, and greatly adds to the rapid healing of the wound and the comfort of the patient.

Dry absorbent dressings should be applied, and kept in position by a T-bandage.

The tied ends of the silkworm-gut sutures should be left long, their free ends should be tied together, and a pad of dressing applied on either side to prevent them from irritating or pricking the patient. The sutures may be removed about the eighth day.

2. Operation for complete rupture.—The steps of the operation are practically the same as for partial repair of the perineum,

FIG. 179.—Rupture of perineum (complete). Line of first incision.

- a. Urethral orifice.
- b. Anterior vaginal wall.
- c. Cervix.
- d. Line of incision for raising vaginal flap.
- e. Mucous membrane of bowel.
- f. Torn orifice of anus.

but in this case the recto-vaginal septum is more or less torn, sometimes as far as the cervix, and the sphincter ani is involved. In most cases the anus will be seen gaping, the mucous membrane of the bowel being exposed and often prolapsed.

Position, instruments, etc., as for the preceding operation.

Operation.—An incision, which is similar in shape to the one made use of in the previous operation, is made. This should be commenced at the lowest border of the torn recto-vaginal septum, and carried upwards on either side. It is not always an easy matter to start the flap-splitting of the torn septum, as it is often bound down and distorted with scar tissue.

The form of the flap and the outline of the incision are shown in Fig. 179. *above*

The lower lateral prolongations of the incision (Fig. 180) are made in order to freshen the ends of the torn sphincter and to free the structures before the rectal sutures are applied.

When the vaginal flap has been raised, it is treated in an exactly similar method to that described for partial repair of the perineum.

The rectum is repaired by the insertion of a series of chromic-gut sutures, according to the method shown in Fig. 180. The first suture is entered at the apex of the tear, the suture being

FIG. 180.—Rupture of perineum. Flap dissected up, and sutures closing laceration in rectal wall introduced, but not tied.

- c.* Vaginal flap raised.
- d.* Raw surface made by raising vaginal flap.
- e.* Line of incision prolonged backwards to expose ends of sphincter.
- f.* Rectal sutures passed.

passed from below upwards, and then each end tied so that the knot lies in the rectum. In Fig. 180 the sutures should not (in being passed) involve the mucous membrane, but just enter the tissues on either side. A sufficient number of these sutures are passed to close the rent in the bowel. By this means the ends of the sphincter are approximated and the anus reproduced.

In order to further strengthen this union, a "purse-string" suture (Fig. 181) may be inserted. Some operators do not think the insertion of rectal stitches necessary. The next stage of the

operation is similar to that of a partial rupture. The deep silk-worm-gut or silver-wire sutures are introduced after the method shown in Fig. 181. When these have been tied, the perineum has the appearance shown in Fig. 182. Redundant portions of skin at the side of the V-shaped incision may be removed with scissors, before passing the deep perineal sutures.

After-treatment.—The after-treatment consists in keeping the wound dry and clean. The catheter may be needed. The bowels should act on the third or fourth day. Great care

FIG. 181.—Rupture of perineum (complete). Laceration in rectum closed, and second series of sutures introduced.

- f. Anus restored.

should be taken after removal of the sutures, on the eighth day, that the patient does not get about too soon.

In some cases of perineal laxity, necessitating operation, complicated with descent of the uterus, it may be advisable to amputate portions of the hypertrophied cervix, or perform hysteropexy, before repairing the perineum.

OPERATIONS ON THE VAGINA.

1. **Malformations.**—Malformations of the vagina include double or septate vagina, congenital absence or defect, and

atresia, congenital or acquired. Malformations of the vagina are frequently combined with abnormalities of the uterus.

Atresia of the vagina may lead to retention of menstrual blood. In congenital atresia, in its most marked form, no trace of a vagina exists, except for some fibrous or muscular bands between the bladder and rectum. Falling short of this, the vagina may be partially perforate, the remainder solid. Less marked forms exist, as a membranous obstruction or perforated diaphragm at one part of the passage.

Acquired atresias are generally traumatic in origin. Most operations are undertaken in order to allow of the escape of the retained menses (hæmatocolpos and hæmatometra). It is often very difficult after such operations to keep the track open, as it is not lined with true mucous membrane.

In cases where the uterus or ovaries are absent or imperfect, no operation is usually necessary. Great care should be taken in attempts to reach the cervix, by dissection in the perineal region, in such cases, not to wound the bladder or rectum.

In rare cases, where the vagina is double, one side may be patent and the other occluded. If menstruation occur, a unilateral hæmatocolpos results.

2. Operations for vaginal fistulæ.—The chief varieties of such fistulæ are—(1) Vesico-vaginal, (2) urethro-vaginal, (3) uretero-vaginal, (4) vesico-uterine or vesico-cervical, (5) uretero-cervical, (6) recto-vaginal. These generally result from sloughing after protracted labour; perforation by instruments is less common. Foreign bodies have ulcerated into the bladder or from the bladder, while vesico-vaginal fistulæ may occur in the later stages of malignant disease of the cervix or bladder. Injuries of the recto-vaginal septum in labour are much commoner than those of the anterior vaginal wall.

Many of the operations devised for the repair of vaginal fistulæ are very complicated, and often necessitate great ingenuity and skill. If some portion of the wound can be got to heal, it is something, and repeated operations may be necessary before the fistula is finally closed. The most difficult cases are those in which the fistula involves the ureter and cervix, or the highest parts of the vaginal fornices. No fixed rules can be laid down for operations in these cases, the main points at issue being—(1) *Paring the edges of the fistula*; (2) *freeing the tissues in order to approximate the pared edges*; (3) *the suturing and closing of the wound*. Preparatory treatment is necessary in most cases where the vagina is sodden with urine. If a recto-vaginal fistula exist as well, this may be closed first. Probably

the best time to operate is six to eight weeks after labour, when the parts are fairly soft and yielding, and not fixed and distorted by scar tissue. If the vesical fistula be a small one, its edges may be drawn together with a tenaculum, the margins freshened, and united by sutures. Large irregular holes into the bladder are very difficult to cure. Many operations have been proposed for urinary fistulae, but only the following will be described :—

1. OPERATION FOR VESICO-VAGINAL FISTULA.—This consists in denuding the margins of the vaginal surfaces and then uniting them by sutures.

Special instruments.—Speculum, lateral retractors, fistula knives and scissors, tenacula, long-toothed forceps.

Position.—The patient is placed in the lithotomy position, with elevated hips, or in the left lateral posture.

Operation.—The posterior vaginal wall is drawn well back by the speculum, and lateral retractors are of great service. One of the most important conditions in such operations is the relief of tension, as it is worse than useless to attempt to cure bad cases unless the edges of the fistula can be approximated when the sutures are in place. The mucosa of the bladder in the region of the fistulous aperture is dissected free from the vaginal walls, and closed by sutures. These are buried by the separate layer of sutures closing the vaginal edges. The detachment of the flexible bladder from rigid vaginal walls, in bad cases, may be of the greatest service before it is in any way possible to attempt to close the fistula. The edges of the fistula are first pared from the vaginal surface; this should not include the mucous membrane of the bladder. Either a knife or scissors may be used for this purpose. The tissues should not be bruised. Long-toothed forceps and sharp hook tenacula are very useful at this stage of the operation.

Passing and tying the sutures.—This is done with fine curved needles and a holder, or by long needles mounted on a handle, the tissues being steadied by a tenaculum as the needle is passed. Especial care should be taken to secure accurate apposition of the surfaces, and to close the whole wound. The angles of the wound are often very difficult to manipulate, especially if the fistula reaches high up in the vaginal fornix. The stitches must traverse the muscular, and not the mucous coats of the bladder. After closing the wound, the bladder should be tested to see if it be water-tight. If silver sutures are used, these are tightened by a wire-twister.

After-treatment.—This consists chiefly in keeping the bladder from becoming distended. In small fistulae, the patient may be

allowed to pass water naturally. The stitches are removed in about twelve to fifteen days.

2. URETHRO-VAGINAL FISTULÆ occur low down near the vaginal orifice; they may be dealt with in the manner described for vesico-vaginal fistula. In *hypospadias* there is no urethra, the bladder opening directly into the vagina.

3. URETERO-VAGINAL FISTULÆ.—These occur high up in the vaginal vault. They result from sloughing after labour, or injury at operations for the removal of the uterus. The sloughing may affect the cervix as well as the vagina, and one or both ureters may be involved.

Sometimes the condition undergoes spontaneous cure; if not, an attempt may be made to close the opening, as in vesico-vaginal fistulæ. If the fistula be unilateral, some operators advise the removal of the corresponding kidney if all other operations fail.

4. VESICO-UTERINE, or, as they should be termed, VESICO-CERVICAL FISTULÆ, generally result from sloughing of the tissues after labour. In this condition there is a persistent hole in the bladder, as well as destruction of part of the ureters and cervix. If a large portion of the cervix and vagina is involved, a *vesico-cervico-vaginal* (or vesico-utero-vaginal) fistula results.

Vesico-cervical fistulæ are usually small. They are best treated by separation of the bladder from the cervix, as in the first stages of a vaginal hysterectomy. This exposes the hole in the bladder and that in the cervix. The fistulous opening into the bladder is now closed by sutures in one or two layers. The hole in the cervix may be left alone.

5. URETERO-CERVICAL FISTULÆ are very rare.

6. RECTO-VAGINAL FISTULÆ.—In this case there is an opening between the vagina and rectum. It generally results from rupture of the perineum in labour, and not from sloughing. It may also result from malignant disease of the vagina, uterus, or bowel. It usually occurs low down in the vagina. In some cases the perineum has been repaired, but has only partially healed, leaving a fistula above this.

Operation.—These cases may be treated on similar lines to vesico-vaginal fistulæ. If the hole is small, the edges may be passed and the opening closed with sutures. If large, it is better to cut through the part of the recto-vaginal septum below the fistula, and then treat the case, as described above, for complete rupture of the perineum. Cases of fistula due to malignant disease are hopeless, and nothing can be done for them.

COLPO-CLISIS, OR CLOSURE OF THE VAGINA.—This is advised

by some operators, if all attempts at repairing the vesico-vaginal septum fail, or if the whole upper part of the vagina has sloughed. It is not satisfactory.

Operation.—The mucous membrane of the vagina is pared away for an inch or more all round the circumference of the vagina below the fistulous opening. The raw surfaces are then brought into contact by silk-worm gut or silver-wire sutures, much in the same way as described above for vesico-vaginal fistula.

Other methods have been devised for the cure of urinary fistulae. Milton's operation of transplantation of tissue, and those described by Stanmore Bishop, Howard Kelly, and Jobert may be looked up in special works devoted to this subject. Extroversion of the bladder is a very rare condition in women, and is described elsewhere. The front wall of the bladder is wanting, and it is accompanied with other malformations.

3. Operations for tumours of the vagina.—Tumours of the vagina are rare, but cysts, lipomata, and fibroids occur. Primary sarcoma and epithelioma are very uncommon. Primary sarcoma is remarkable in that it occurs in very young children as well as adults. Malignant disease of the vagina is more often secondary to that of the cervix, urethra, and vulva; operative treatment is disappointing. Vaginal cysts occur as simple mucous cysts, or are developmental in origin. They should be dissected out, a proceeding which is not always an easy matter. Peri-urethral cysts also occur in the vagina. Vaginal fibroids generally grow singly in the anterior wall of the vagina, near the middle line, anywhere from the urethral orifice to the vaginal fornix. They are best treated by enucleation.

4. Colporrhaphy, or elytrorrhaphy.—In this operation portions of the mucous membrane of the vagina are dissected away, in order to narrow the passage. Colporrhaphy is done for the cure of cystocele, rectocele, and prolapse of the uterus.

Some operators advise that the tissue should be removed from the anterior aspect, others from the lateral, others from the posterior portion of vaginal walls. Anterior and posterior colporrhaphy are the operations usually performed.

ANTERIOR COLPORRHAPHY.—In this operation a portion of the mucous membrane of the anterior vaginal wall is dissected away. It should be a large portion. The shape of the piece removed matters little. Care must be taken not to injure the bladder. The sides of the denuded area are then closed with sutures, which brace up the vaginal wall. Unfortunately, the

tissues soon stretch again if subjected to strain, as in prolapse of the uterus. The operation may sometimes be a useful adjunct to perineorrhaphy or hysteropexy, in bad cases.

POSTERIOR COLPORRHAPHY.—The piece of tissue in this case is removed from the posterior vaginal wall. It is a good operation in women who have passed the climacteric, but in order to be of use a large area of the mucous membrane must be taken away.

Position.—In this as well as in anterior colporrhaphy the patient is placed in the lithotomy position.

Special Instruments.—Clover's crutch, a duckbill speculum, long-toothed forceps, curved and angular scissors, and needles of various sizes.

The sutures may be of chromic gut, silk-worm gut, or silver.

Operation.—The area of mucous membrane to be removed is mapped out from the vulvar orifice upwards. The incisions must not be too deep, or the bowel may be wounded. The mucous membrane is now carefully dissected away within the limits of the area mapped out, and the cut edges brought into apposition by sutures. This narrows the vaginal orifice. The operation is often combined with anterior colporrhaphy, as well as with perineorrhaphy, for the relief of prolapse of the uterus. If a wedge-shaped piece of the vaginal flap be removed, as described in the operation for repair of the perineum, and the edges apposed by sutures, the operation may be described as *colpo-perineorrhaphy*.

A modification of anterior and posterior colporrhaphy is sometimes used for the cure of hopeless prolapse in women past the child-bearing period.

In this operation the prolapsed uterus and vaginal walls are pulled down by volsellum forceps, and a vertical band of mucous membrane, an inch wide, is dissected away, first on the anterior surface of the prolapsed mass, and then on the posterior. The incisions for the separation of these bands of mucous membrane end below at the cervical orifice.

The cervix is now partially replaced, and the lateral raw edges of the denuded areas are apposed, first on one side and then on the other, by sutures. More of the prolapsed mass is replaced, and more lateral sutures applied, till the lowest portion of raw area is reached. Thus a firm antero-posterior septum is formed of stitched mucosa in the centre of the vagina, from above downwards. This effectually prevents any descent of the walls.

5. Colpotomy.—This operation consists in cutting into the vaginal fornices, either in front or behind the cervix, much as in

the preliminary stages of vaginal hysterectomy. By this means the peritoneal cavity is opened either between the bladder and the cervix, or in the region of Douglas's pouch.

The operation is done for exploratory purposes and for the removal of diseased ovaries and tubes, small ovarian tumours, and extra-uterine sacs. Anterior colpotomy is one of the steps in vaginal fixation of the uterus for the cure of retroflexion.

It is claimed that colpotomy is a better operation than abdominal section in cases of disease of the uterine appendages, and for the removal of small tumours, in that it leaves no external scar, and entails no risk of ventral hernia; but, on the other hand, against colpotomy is the objection that the space for operation is small. Certainly the parts cannot be exposed as effectively by colpotomy as by abdominal section, and in my opinion the latter operation is to be preferred in nearly all cases.

ANTERIOR COLPOTOMY.—The patient is placed in lithotomy position, the cervix seized with volsellum forceps and drawn downwards. A sound is introduced into the bladder to define its limits. The mucous membrane of the vagina is then divided transversely, as in the first stage of vaginal hysterectomy, and the bladder gradually detached from the cervix, from below upwards. This is continued till the anterior peritoneal pouch is reached. This is caught by long pressure forceps, pulled down and carefully opened, first with scissors, and then widened by tearing with the fingers. The fingers introduced through the opening thus made, can explore the utero-vesical pouch, uterus, and appendages. Small tumours, or a diseased tube or ovary, can be removed by this method. The wound is then closed by vaginal sutures or drained by a strip of gauze.

POSTERIOR COLPOTOMY.—This consists in opening Douglas's pouch by an incision through the vaginal vault posterior to the cervix.

The patient is placed in lithotomy position, the cervix held forwards, and a transverse incision is made behind the cervix at the upper limits of the vaginal portion. The vaginal flap is steadied by forceps, while the finger gradually separates the posterior vaginal wall from its attachment to the cervix. The posterior peritoneal pouch is at length exposed; this is caught with another pair of forceps and opened carefully, in order not to injure any bowel which may be in the pouch. The peritoneum is then further opened by tearing with the fingers, and Douglas's pouch explored. It is a good plan to secure the cut edge of the peritoneum to that of the vagina posteriorly, as

the peritoneum is apt to slip upwards and get lost during any subsequent manipulations. The appendages, posterior aspect of the uterus, and broad ligaments can be fairly easily reached by this method, or small tumours removed. If, however, serious adhesions exist, the operation of removal of a tumour is a dangerous matter, and such cases are best treated by abdominal section.

A pelvic effusion or abscess, or a retro-uterine hæmatocele, are easily opened by posterior colpotomy. The wound may finally be closed by sutures or drained by gauze, according to the conditions found at the time of operation.

6. Vaginal fixation of a retroflexed uterus.—The first stages of the operation are the same as those for anterior colpotomy. Some operators prefer an antero-posterior incision of the vaginal mucous membrane instead of a transverse, prior to separating the bladder. The bladder is separated from the vaginal walls as well as from the cervix, and pushed up out of the way. Its limits should from time to time be defined by the bladder sound. The anterior pouch of peritoneum is next opened and the uterus anteverted, if necessary, by a sound. A curved needle is next passed through the anterior aspect of the uterus as high up as possible, each end of the suture passing through the edges of the vaginal incision. Several sutures may be necessary, and, when these are tightened, the uterus is held forward, and the vaginal incision closed at the same time. The sutures may remain ten days or a fortnight before removal; silkworm-gut answers best.

It may not always be necessary to open the peritoneum; this lessens the risk of the operation, but it is less effective, since the body of the uterus is not reached by the sutures. Vaginal fixation is probably better performed on women after the climacteric.

OPERATIONS ON THE UTERUS.

1. Dilatation of the cervix.—This may be necessary in order to explore the cavity of the uterus, and for the removal of products of conception, growths or polypi, for curetting, and in certain cases of dysmenorrhœa. It is the most frequently performed operation in gynæcological practice. In nearly all cases the cervix is dilated with metal bougies or dilators. These have the advantage that they can be sterilised. Tents are sometimes used as a preliminary measure, but they are not often necessary, unless the cervix is very rigid or wide dilatation is necessary.

Great care should be taken to secure as perfect asepsis as possible.

Special instruments. — Clover's crutch, Sims' or Auvar'd's speculum, volsellum forceps, a set of metal dilators arranged in series, uterine sound, speculum forceps, sponge-holders, and catheter.

Position. — The patient is anaesthetised and placed in lithotomy position, the legs being separated by Clover's crutch.

Operation. — The vagina is carefully cleansed, and the duckbill speculum introduced posteriorly. The anterior lip of the cervix is seized with volsellum forceps and steadied. The length and direction of the uterine cavity should be determined by the sound.

The dilators are now passed one after another into the cervix, until the necessary amount of dilatation is obtained.

In some cases, especially after abortion, or if the uterus contain a growth, this is an easy matter; in others, the tissues of the cervix are very rigid. If a growth of the body of the uterus be suspected, it may be necessary to dilate the cervix sufficiently to admit the finger. Care must be taken, in dilating the cervix, not to use too great force, or to pass one dilator after another without giving time for the tissues to relax.

Most of the difficulty in dilatation is with the internal os. If due care be not taken, the cervix may be very severely torn laterally, or the uterus perforated. Sometimes difficulty is met with owing to smallness of the external os; if so, it may be incised laterally for a short distance.

After dilating the cervix to the necessary amount, the cavity of the uterus can be explored with the finger, the cervix being steadied with the volsellum forceps. Pushing the fundus down with the other hand on the abdomen greatly facilitates the process. Following upon dilatation, one of the following operations may then be performed:—

2. Curetting. — The curette is a special instrument of which there are many modifications. It should not be made too sharp. Some curettes are hollow, and permit of the tube from a douche can being attached to the handle, so that the instrument also flushes the area of operation. The curette is a useful instrument, but is much abused, and in septic conditions of the endometrium may be positively dangerous.

In scraping, too much force should not be used, but every portion of the uterine cavity should be explored, especially the regions of the orifices of the Fallopian tubes.

After curetting, the uterus may be washed out with an anti-

septic solution or swabbed out with iodine, by means of cotton-wool on a probe, or held in forceps, care being taken that no pieces of wool be left behind in the uterus. If the bleeding be free, the cavity may be plugged with a long strip of ribbon gauze. This is removed in twelve to twenty-four hours. The plug sometimes causes great pain.

3. Repair of lacerations of the cervix (*trachelorrhaphy*).—

This operation is not often performed, but may be of some use in cases of extensive tears of the cervix with ectropion of the mucous membrane. The condition is often associated with cervical catarrh, erosion, and chronic inflammatory enlargement of the parts.

Special instruments.—Duckbill speculum, vaginal retractors, tenaculum forceps, long-toothed dissecting forceps, volsellum forceps, fine long-handled scalpels and scissors, mounted angular needles, sharp hooks, etc.

Position.—The patient is placed in the lithotomy position.

Operation.—The cervix is drawn down to the vulval orifice, if possible. If the cervix is fixed by old scar tissue, the operation is more difficult. The torn lips of the cervix are now separated by volsellum forceps, and with the scalpel or scissors a strip of tissue is dissected off the exposed surface on each side, from above downwards, parallel with the portion of mucous membrane in the middle line. The upper angles of the tear are the most difficult to deal with. Each lip is treated in this way, and the raw surfaces apposed by bringing the lips of the cervix together. First one side of the cervix and then the other is now sutured from above downwards, till it more or less assumes its original shape, leaving the cervical canal free. There is thus a row of tied sutures on each lateral margin of the vaginal cervix. These may be allowed to remain in for ten days to a fortnight before removal. If chromic-gut sutures are used, they may be left to be absorbed.

4. *Removal of mucous polypi of the cervix.*—These are best removed by twisting them off with forceps. Their pedicle sometimes contains a fairly sized vessel, which may give rise to troublesome oozing if the polypus is merely cut off with scissors.

5. *Removal of fibroid polypi.*—In most cases the polypus protrudes from the cervix, so that preliminary dilatation is unnecessary.

Beyond the instruments described above, long-curved scissors and some strong tenaculum forceps are needed. The length and position of the uterine cavity should first be carefully

determined, as an inverted uterus has been mistaken for a polypus.

The tumour is steadied with tenaculum forceps, and the pedicle cut through with scissors. If there is bleeding, the uterine cavity is plugged with gauze. Sometimes a polypus is associated with partial inversion, and if care be not taken a hole may be made into the uterine wall.

6. Sessile fibroids of the cervix.—These are best dealt with by enucleation. The capsule is incised and the tumour carefully shelled out with the finger. The cavity is then plugged with gauze.

7. Removal of intra-uterine fibroids by the vagina.—The cervix is first dilated, and the relations of the tumour carefully determined.

Small pedunculated tumours may be removed by division of their pedicle, though there is often some difficulty in getting the tumour through the cervix, even after its pedicle is divided.

Sessile submucons tumours, if small, may be enucleated and twisted out of their bed entire, after division of the capsule.

Larger tumours may be removed by "*morcellement*." In this operation the tumour is removed piecemeal through the cervix. The cervix is dilated, and the dimensions of the tumour ascertained. Its capsule is divided, and the tumour cut to pieces and removed bit by bit. The operation takes a long time, and is not without risks. Strong tenaculum forceps are used to grasp the tumour. As the operator cuts away its lowest portions a fresh grasp is taken, and more and more of the tumour removed. Some operators use strong parrot-bill forceps with cutting edges; by this means piece after piece of the fibroid may be rapidly cut away, till finally the whole mass is removed.

In some cases it may be necessary to divide the cervix upwards as far as the internal os, before attempting to deal with the fibroid. The division may be made anteriorly, having first reflected the bladder, as in vaginal hysterectomy, or the cervix may be split up on either side in the latter case. It may be well to ligature the uterine arteries first. After the operation, the incisions into the cervix are closed with sutures. It is doubtful if large tumours should be treated in this way, owing to the risks of damaging the uterus, subsequent sloughing, and infection. Fibroids larger than a foetal head (if they need treatment at all) are better removed by the abdominal method.

8. Removal of the cervix uteri.—This operation is under-

taken for malignant disease, localised to the cervical tissues, and for elongation, and hypertrophy. Removal of the cervix is one of the many operations advised for the cure of prolapse.

In cancer it is far better to remove the whole uterus, though in the hands of some operators good results seem to have been obtained by removing the cervix only, at the level of the os internum.

Special instruments.—Clover's crutch, Sims' speculum, retractors, bladder sound, volsellum forceps, pressure forceps (large and small), Paquelin's cautery or cautery irons, pedicle needles.

Position.—The patient is placed in the lithotomy position, the limbs being separated by Clover's crutch. The operator sits facing the perineum, an assistant stands on either side.

Operation.—A Sims' (Fig. 183) or Anvard's speculum is intro-

FIG. 183.—Vaginal hysterectomy. Sims' speculum.

duced into the vagina, and the cervix exposed. The cervix is seized with volsellum forceps, or held by a temporary stout silk ligature passed through the vaginal portion. Some operators, in dealing with cancer, close the cervix by sutures first, to prevent the escape of the uterine contents over the field of operation. If the cancer involves the canal, as much of the growth as possible may be first scraped away or destroyed by the cautery. Of course these measures are not necessary in simple cases of elongation or hypertrophy. The next stage of the operation consists in the separation of the cervix. The relations of the bladder are constantly determined, both now and during the operation, by means of the bladder sound.

Having grasped the cervix by volsellum forceps (or holding it by the stout silk ligature, passed as described above), the mucous membrane is divided across the front of the cervix, as in Fig. 184, *a*.

The bladder is now carefully separated from the cervix, partly with the fingers and partly by scissors, and pushed upwards behind the symphysis. Great care must be taken not to perforate the bladder, and to separate it laterally as well as anteriorly. The separation is continued until the reflection of the peritoneum is reached, but this is not opened.

The posterior vaginal incision is now made, as in Fig. 184, *b*, the cervix during this stage being held forwards. The cut edge of the vaginal wall is held by forceps, while the operator separates the cervix from its posterior attachments, but Douglas's pouch is not opened.

FIG. 184.—Vaginal hysterectomy. Line of anterior and posterior incisions.

a. Anterior.

b. Posterior.

The cervix at this stage is attached laterally to the bases of the broad ligaments. The ends of the anterior and posterior vaginal incisions are now united, and the lowest portions of the broad ligament ligatured. This is effected by passing the pedicle needle (threaded) through the lowest portion of the broad ligament close to the cervix; the loop is seized, and the needle withdrawn. One end of the ligature is drawn through, and the ends firmly tied.

The tissues between the cervix and the ligature are then divided.

The opposite broad ligament is treated in a similar way.

If necessary, a second or third ligature may be passed, and more of the broad ligaments tied off, till the level of the peritoneal pouch is reached.

The uterine arteries are thus commanded, and the cervix may now be amputated by a scalpel or scissors.

If there is any bleeding at this stage, the vessel may be tied or a clamp left on; sometimes the cut edges of the vaginal wall give rise to troublesome bleeding, and this should be remembered, otherwise the operator may think that the hæmorrhage is taking place from the broad ligaments.

Instead of tying off the broad ligaments, some prefer to use

clamps from the first. These are allowed to remain on for twenty-four to forty-eight hours.

After removal of the cervix (in non-malignant cases), the cut vaginal wall may be united to the stump of the cervix by interrupted sutures, the canal of the cervix being preserved.

In malignant cases this is not necessary; in fact, some operators further destroy the surface of the stump with the actual cautery, or perform the whole operation by means of this instrument.

The vagina is now sponged out, and plugged lightly with gauze.

The catheter should finally be passed, to ascertain if any injury to the bladder has occurred.

By keeping close to the cervix during the operation, it is unlikely that the ureters will be injured.

9. Complete removal of the uterus by the vagina—vaginal hysterectomy.—Removal of the uterus by the vagina is most commonly performed for malignant disease, either of the cervix or body; this includes such conditions as carcinoma, sarcoma, deciduoma, and adenoma malignum. Small fibroid uteri, giving rise to intractable bleeding, are sometimes removed by this route. Vaginal hysterectomy may be indicated in rupture or perforation of the uterus, procidentia, and in severe septic conditions of the endometrium.

Special instruments.—The instruments are the same as for removal of the cervix, as are also the preliminary steps of the operation itself.

Position.—The patient is placed in lithotomy position; the operator faces the perineum, and the external parts and vagina are thoroughly disinfected.

Operation.—The Sims' or Auvard's speculum is passed, and the cervix exposed. Lateral vaginal retractors are also useful.

As in amputation of the cervix, this is seized with volsellum forceps, or held by strong silk ligatures and drawn downwards as far as possible.

If a large growth obscure the cervix, this may be first cut or burnt away, or the cervix may be sewn up to prevent discharges infecting the field of operation.

The bladder is then separated from the cervix by a transverse incision, as described in the previous operation, and pushed upwards till the peritoneal pouch is reached. This is steadied by forceps and carefully opened, the opening being further enlarged by the fingers.

The posterior incision is now made, and Douglas's pouch

opened by picking up the pouch with forceps and cutting into it with scissors. Bowel sometimes lies in the pouch, and may be accidentally wounded. The opening into Douglas's pouch is also further enlarged by the fingers.

The cervix is now freed laterally by uniting the vaginal incisions, and the lower portions of the broad ligaments tied off or clamped, thus securing the uterine arteries.

More and more of the broad ligaments are now transfixed and tied on either side, and after division the uterus will be found to come lower and lower into the vagina.

It is well from time to time, as the ligatures are being passed, to examine the relation of the uterus to the broad ligaments and bladder, by passing the fingers either through the anterior or posterior openings into the peritoneum. If there is difficulty in reaching the upper parts of the broad ligaments, the finger may be hooked over their upper edge. Any remaining tissues are then ligatured and divided. The uterus is now free.

In difficult cases, owing to fixity, or the size of the uterus, it may be advisable to tie off one broad ligament first, from below upwards, and then turn the uterus out sideways into the vagina; the opposite broad ligament may then be exposed, and tied from above downwards.

Some operators prefer to antevert or retrovert the fundus, through the peritoneal openings, into the vagina, during the later stages of the operation. This easily allows of the upper portion of the broad ligament to be ligatured, but it can only be done when the uterus is small. After removal of the uterus, all bleeding points must be tied or clamped with forceps. The ligatures of each side (which should be left long) are now tied together in two groups, and the vagina sponged out. The peritoneal opening is then lightly plugged with gauze. Pro-lapse of the bowel is not common, but should be guarded against. If this is feared, it may be well to approximate the anterior and posterior vaginal flaps with a central suture, leaving the lateral portions open. The vagina may also be lightly filled with a strip of gauze. If clamps are used instead of ligatures, these are left *in situ* for twenty-four to forty-eight hours.

Difficulties and dangers of the operation.—Among the difficulties of the operation are narrowness of the vagina and fixity of the cervix. The bladder, ureters, or bowel may be injured, and hæmorrhage during and after the operation may give rise to serious trouble.

Difficulties also arise from the size of the uterus ; this may be due to malignant disease of the body, pyometra, or uterine fibroids.

With regard to fibroids associated with cancer of the cervix, if the size of the body of the uterus be not larger than a ten or twelve weeks' pregnancy, it can be removed by the vagina.

Larger tumours than this should be removed by abdominal section.

Cancer of the body may enlarge the uterus in a similar way.

Pyometra may be opened and drained for a time, before removal of the uterus is attempted.

If the uterus cannot be brought down, on account of its size, the whole organ may be split in half and each portion removed separately, or the uterus may be removed by *morcelement*.

In a bad case, it may be better to free as much of the uterus as possible from the vagina, and then remove the tumour by abdominal section.

Causes of death after vaginal hysterectomy.—The chief are—hæmorrhage, septic peritonitis, cystitis, thrombosis of the pelvic veins, and pulmonary embolism. Injury to the bladder and bowel may give rise to trouble later, and intestinal obstruction sometimes occurs.

10. Abdominal hysterectomy for cancer of the uterus.—The abdominal route for removal of the uterus for cancer does not at present give such good results as the vaginal method. Much depends upon the seat and extent of the disease. In cancer of the cervix, vaginal hysterectomy seems to yield excellent results ; but in cancer of the body, especially if the uterus be enlarged, pan-hysterectomy is the better operation. It may be performed entirely from the abdomen, or in combination with vaginal separation of the cervix.

Of late, very extensive abdominal operations have been performed for uterine cancer, more or less in imitation of operations on cancerous breasts associated with the removal of the axillary glands, infected cellular tissue and muscles. In these operations, not only is the uterus removed, but the broad ligaments, iliac glands, and infected parametric tissues as well. The ureters are defined by catheterisation from the bladder, and are dissected out and preserved. Douglas's folds, with their neighbouring tissues, and the floor of Douglas's pouch, have also been removed, together with the upper part of the vagina. The after-results of such heroic proceedings have not been very encouraging.

OPERATIONS ON THE OVARIES AND UTERINE APPENDAGES.

1. Ovariectomy (abdominal).—This operation consists in the removal of tumours of the ovary, broad ligament, and parovarium, by an incision through the abdominal wall.

An ovarian tumour should be removed as soon as it is diagnosed. It is useless to wait for risks in connection with the tumour itself, or its effects upon neighbouring organs. It is, of course, possible that some cysts cannot be removed, either on account of their malignant character, or from hopeless adhesions to important structures. An ovarian tumour is liable to inflammatory changes, torsion of the pedicle, rupture, and malignant changes. Sarcoma of the ovary is not uncommon in young girls and children.

The general health of the patient is also important, and the condition of the heart, lungs, and kidneys must be taken into account in prognosis. Careful preparation of the patient before operation is a very essential point; but for this and other clinical details, special books on the subject should be consulted.

Special instruments.—Scissors (straight and angular), trocar and tubing for

tapping the cyst, pedicle needle, and cyst forceps. All instruments and sponges should be counted before and after operation.

Position.—The patient may be placed upon her back as in ordinary abdominal operations, but the Trendelenburg (Fig. 58) or raised pelvic position is often of the greatest assistance.

Operation.—*Parietal incision and exposure of tumour.*—An incision 2 to 3 in. long (Fig. 185) is made in the median line, between the umbilicus and the pubes. The skin and fat are first divided, and the aponeurosis of the recti exposed. All bleeding is arrested with forceps. The interval between the recti is now sought for, and the muscles separated for the length of the incision. The posterior sheath of the rectus is exposed

FIG. 185.—Ovariectomy. *a.* Position of parietal incision.

and divided, and the subperitoneal fat exposed. This varies much in thickness, and must be cut through with care, successive layers being lifted up with dissecting forceps before division. The peritoneum is then exposed, and is picked up and divided in the same way. As soon as the peritoneum is divided, air enters, the intestines or cyst fall away, and the belly wall can be lifted up by the fingers. The peritoneum is then divided on two fingers for the length of the incision, care being taken below not to injure the bladder, which is often much displaced.

In a simple case it is easy enough to open the abdomen and to expose the glistening cyst; but if the peritoneum is thickened, or there are dense adhesions, it is sometimes difficult to decide when the cyst itself is reached. The incision may even be carried through the cyst wall.

In such cases it is better to attempt to open the peritoneal cavity higher up. After exposing the tumour, it should be carefully examined to see if it be cystic or solid, and the number and variety of adhesions noted (if any). The character of the tumour is also important, whether inflamed, dermoid, or even malignant; and if there are malignant deposits elsewhere. It is much better not to *attempt* removal in hopeless cases, as an unfinished ovariectomy is most distressing to all concerned.

Treatment of adhesions.—If recent, these are easily sponged away or separated with the hand. More serious adhesions may be dealt with after the cyst is emptied. Portions of omentum may require ligature before division. Adhesions to intestine need especial care; it may be better even to leave a piece of the cyst wall adhering to the bowel than to run the risk of tearing or perforation.

Peritoneal adhesions in the pelvis are often very troublesome, and the ureters or large pelvic veins may be damaged. The bladder may also be wounded if its limits are not borne in mind.

FIG. 186.—Trocar for evacuating ovarian cyst.

Emptying the cyst.—This is sometimes quite an easy matter, and it may be tapped by a trocar, the cyst being drawn out of the incision as the fluid is evacuated. Its contents should not be allowed to enter the abdominal cavity.

In some cases the fluid is very viscid, or the cyst is so multilocular that it cannot be emptied in this way. Dermoids contain hair and sebaceous material that will not run through a trocar. In multilocular cysts, the secondary loculi may be broken down by the fingers, by enlarging the opening into the cyst, or very thick material extracted by the hand.

Dermoids and inflamed cysts, of small size are better extracted whole, by enlarging the abdominal wound.

Some tumours necessitate enlargement of the abdominal wound, on account of their being almost entirely solid. It is far better to enlarge an abdominal wound than to work in darkness and uncertainty in difficult cases.

Treatment of pedicle and removal of tumour.—When the cyst has collapsed and been drawn up out of the wound, the pedicle has to be secured. It consists of Fallopian tube and the parts of the broad ligament containing the ovarian vessels and ovarian ligament.

Sometimes the pedicle is long and thin, and may easily be secured by transfixing it, at a point devoid of vessels, with a pedicle needle armed with silk of sufficient thickness. It is a mistake to use too thick silk in

tying ovarian pedicles. The loop of silk is next divided and held, and the needle withdrawn. Two threads thus pass through the pedicle; these are interlocked and firmly tied, one on either side. The interlocking of the silk loops prevents the pedicle splitting; this sometimes gives rise to troublesome hæmorrhage.

FIG. 187.—Ovariectomy. Cyst forceps.

Some operators put a final circular ligature round the pedicle, for greater security. The tumour is now cut away, leaving a stump of sufficient size not to slip through the ligature loops. The cut surface should be examined for any oozing before being dropped back into the abdomen. Large vessels in the stump may be ligatured again separately, for additional security. The opposite ovary should always be examined to see if it is also diseased. Small cysts in the periphery of an otherwise healthy ovary may be excised by a wedge-shaped incision, and the cut surface closed by fine silk. This is important, as it sometimes enables the operator to leave a piece of healthy ovary in a case where the other ovary *has* to be removed for hopeless cystic degeneration.

Large pedicles, and especially broad short pedicles, are sometimes very difficult to secure. They may need a second, or even a third, transfixion with looped interlocked ligatures. All knots should be securely tied, and loose ends avoided by cutting as near the knot as can be done with safety. Sometimes the pedicle is so short, and the cyst so large and so dragged upon, that it is impossible to ligature the pedicle with safety before the main mass of the tumour has been cut away. In such cases the pedicle may be clamped for a time with large pedicle forceps, the cyst removed, and then the pedicle held up and the ligatures passed by transfixion below the clamps.

As the clamps are gradually relaxed, the ligatures are firmly tied. Slipping of the ligatures of an ovarian pedicle is a serious matter, and the pedicle should always be finally examined before closing the abdomen. If the ligatures have slipped, the pedicle must be retied below the seat of the original ligature.

Sessile ovarian tumours have no pedicle, and cannot therefore be drawn out of the abdominal wound without being enucleated in the layers of the broad ligament. Tumours

FIG. 188.—Ovariectomy.
Pedicle needle.

of this sort should be recognised, if possible, before they are tapped. Enucleation is performed by dividing the capsule of peritoneum which can be moved over the cyst beneath. The capsule can often be recognised by the strands of unstriped muscular fibres ("uterine platysma") which it contains. When the right layer is reached, the whole tumour is easily shelled out. It may be tapped at once, or later, according to its size.

The walls of the capsule often contain large vessels, which need to be tied. The capsule itself may be dealt with by removing as much as possible, ligaturing the remainder, and finally closing the opening by purse-string ligatures; or if too large and deep, and the bleeding troublesome, its edges may be secured to the margins of the abdominal wound, and its cavity drained for twenty-four hours or more, with gauze.

False capsules sometimes occur, which are very puzzling, covering and embedding an ovarian tumour. They mostly consist of peritoneal lymph and inflammatory adhesions, though it should be remembered that intra-ligamentous tumours sometimes burrow beneath and displace the peritoneum to an extraordinary extent. In performing enucleation, the bladder, ureters, rectum, sigmoid flexure, cæcum, vermiform appendix, or large blood vessels may be wounded.

Cleansing the peritoneum.—The peritoneum should be cleansed of all blood clot or any material that may have escaped during the operation. It is a good plan to wash the cavity of the pelvis out with warm sterile water or saline solution. Care should be taken to guard against infection of the peritoneum in burst papillary cystomata.

Suppurating necrotic cysts are also very dangerous on account of the fluid they contain.

Closure of the abdominal wound.—This may now be closed either by one row of silkworm-gut sutures, which pass through skin, muscle, and peritoneum, or by securing the different layers separately. If the layers are sewn up separately, the peritoneum is first closed by interrupted sutures of fine silk. The sheaths of the recti are then approximated by interrupted sutures of catgut; and, lastly, the skin wound is closed with interrupted sutures. Drainage of the abdomen may be required after ovariectomy, when septic material has escaped into the peritoneal cavity, or when there is free oozing of adhesions, but the tendency of modern times is to employ it less and less. It must be left to the judgment of the operator. Glass tubes or gauze drains are mostly employed.

Accidents during ovariectomy.—The following may be enumer-

ated, but for their treatment special works on the subject must be consulted :—(1) Syncope and shock ; (2) vomiting ; (3) separation of the parietal peritoneum ; (4) rupture of the cyst ; (5) injuries to viscera, such as the bladder, ureter, intestines, or gravid uterus ; (6) severe hæmorrhage ; (7) leaving instruments or sponges behind ; (8) tetanus ; (9) septic parotitis ; (10) septic peritonitis ; (11) insanity ; (12) thrombosis and embolism.

After-treatment and sequelæ.—This is a very important matter, but, as remarked above, in considering the accidents of ovariectomy, special works on the subject must be referred to, as this belongs to the clinical rather than the merely operative side of the question.

2. Removal of the uterine appendages—oöphorectomy.—

In this operation the ovaries and Fallopian tubes are removed by abdominal section.

Indications.—The number of cases which justify removal of the appendages is very small, and the operation should never be undertaken except as a last resource in diseases of these organs. It is an operation which has been greatly misused, and the part played by neuroses in this matter must be duly considered.

The appendages are removed for—

1. DISEASES OF THE TUBES.—Inflammatory conditions, such as pyosalpinx, hydrosalpinx, hæmatosalpinx, and tubo-ovarian abscess ; also in tuberculous salpingitis, tubal pregnancy, and tumours of the Fallopian tube, such as papilloma and cancer.

2. DISEASES OF THE OVARIES, such as abscess, apoplexy, hernia, and prolapse of the ovary. Tumours and cysts have been discussed under ovariectomy.

3. IN THE TREATMENT OF UTERINE FIBROIDS.—Oöphorectomy for fibroids has justly fallen into disuse. It is much better to remove fibroids (that necessitate removal) by abdominal section, leaving the ovaries *in situ*.

4. DYSMENORRŒA AND VARIOUS NEUROSES.—The results of removal of the ovaries for dysmenorrhœa is disappointing, while with regard to hysteria, epilepsy, and insanity, the operation is not justified by the results obtained.

5. OSTEO-MALACIA.—In some cases of this disease, recovery or improvement has followed removal of the ovaries.

6. INOPERABLE CANCER OF THE BREAST.—The justifiability of the operation in this condition is still under consideration.

Operation.—Instruments, position, etc., are much the same as for ovariectomy. The raised pelvic position is often of the greatest assistance. After opening the abdomen, the fundus

uteri should first be sought for, and from this point the Fallopian tubes and ovaries then defined. One or other tube and ovary is now lifted up and drawn out of the wound, and the pedicle treated as in ovariectomy. All traction should be relaxed as the interlocked ligatures are tightened and tied. The other side is treated in a similar way.

In uncomplicated cases this is an easy proceeding; but when the tubes are filled with pus, or both tube and ovary are matted down to the pelvic floor and adjacent bowel, great care must be taken in separating and raising the diseased parts.

If the tubes be found distended with pus or other fluid, they should be, if possible, removed whole. Infection of the peritoneum must be carefully guarded against. This results either from the escape of the contents of the tube, or the pedicle itself may be diseased. The pedicle may also slough and infect the ligatures, giving rise to an abscess of the stump.

Hæmorrhage is sometimes troublesome in cases where many adhesions have to be separated, or if there is difficulty in tying the pedicle. Separate vessels may be ligatured, but if the oozing goes on, the pelvis may have to be plugged with gauze and drained through the abdominal incision. The after-treatment is the same as in ovariectomy. Cases of pelvic abscess pointing towards the vagina are preferably opened by that route.

The treatment of tubal pregnancy will be considered later.

ABDOMINAL OPERATIONS FOR FIBROMYOMATA OF THE UTERUS.

Removal of a fibroid uterus by abdominal section—abdominal hysterectomy.—Uterine fibroids are removed for hæmorrhage, pressure symptoms, size, rapid growth, or on account of the complications they give rise to. It must be remembered that a fibroid does not by its mere presence justify operation. It must be accompanied by symptoms that are dangerous, or be such a source of discomfort, from its size and position, that it prevents the patient from leading an ordinary existence or earning her own living.

Fibroids associated with pregnancy may lead to the most grave conditions, and their treatment necessitates careful consideration, especially if they obstruct the pelvic outlet.

There are three methods by which fibroid uteri are removed: in two, the hysterectomy is partial; in the third, complete. They are—

(a) Supra-vaginal hysterectomy with extra-peritoneal treatment

of the stump. (b) Supra-vaginal hysterectomy with intra-peritoneal treatment of the stump. (c) Total hysterectomy (pan-hysterectomy).

(a) SUPRA-VAGINAL HYSTERECTOMY WITH EXTRA-PERITONEAL TREATMENT OF THE STUMP.—This operation has fallen into disuse,

FIG. 189.—The viscera of the female pelvis, as they appear when seen from above and in front.—After TESTUT.

owing to the improved methods of treating the pedicle by the intra-peritoneal methods.

In the extra-peritoneal treatment of the stump, the tumour was lifted out of the abdomen till its pedicle was exposed. This was then transfixed with two stout pins, and the wire of a Kœberle's serre-nœud passed beneath them, and carefully tightened. The tumour was then cut away above the pins; and

these, together with pins and serre-nœud, secured in the lower angle of the abdominal incision, and the abdomen closed in the usual way. The stump, which was of course extra-peritoneal, gradually sloughed away till the pins and wire could be removed. Convalescence in these cases was tedious, but the operation in experienced hands yielded good results.

(b) SUPRA-VAGINAL HYSTERECTOMY WITH INTRA-PERITONEAL TREATMENT OF THE STUMP.—In this, the fibroid uterus is removed with a portion of the supra-vaginal cervix. The ovaries and tubes, if possible, should be preserved *in situ*.

Operation.—The abdomen is opened by a free incision in the middle line, as in ovariectomy. In large tumours the incision may extend from the ensiform cartilage to the pubes. The Trendelenberg position is often very useful. When the peritoneum is opened, the intestines should be protected by sponges or cellular pads, and the size and relations of the tumour carefully made out. All adhesions should now be dealt with, ~~and~~ the tumour, if possible, lifted out of the abdomen. This may not be possible at this stage, till portions of the broad or round ligaments have been divided and secured.

The broad ligaments are ligatured in the following way:—The one most easily dealt with is transfixed with a pedicle needle, armed with stout silk. This is done, if possible, on the uterine side of the ovary, which should be left. This ligature secures the ovarian artery. The uterine side of the broad ligature is clamped, and the tissue between this and the ligature may now be divided. Sometimes the tension is so great that the knot cannot be securely tied till a portion of broad ligament has first been divided. A second and even a third ligature is passed through the broad ligament lower

FIG. 190.—Hysterectomy. Relative position of structures in broad ligament, as shown in an antero-posterior section.—After TESTUT.

- C. Attachment of ovary to broad ligament.
- D. Round ligament of uterus.
- E. Uterine artery and veins.
- F. Position of ureter.

down, and firmly tied, the proximal portion being clamped with forceps.

The round ligament is generally included in these ligatures, but it may be wiser to tie it off separately, as it often contains a large vessel, and may be very tightly stretched over the tumour.

The opposite broad ligament is now treated in a similar way.

The next step consists in the reflection of the flap of peritoneum and bladder from the front of the uterus. An incision is made across the front of the uterus, from side to side, about half an inch above the line of attachment of the bladder. Its distal ends meet the incision in the broad ligaments. This flap is now carefully turned down with the bladder. If the proper cellular layer is reached, this is an easy matter, but the peritoneum is sometimes very adherent to the front of a fibroid uterus, and needs careful dissection.

A similar flap may be turned down from the back of the uterus. If the flaps are too large after removal of the tumour, they can easily be diminished in size afterwards. When these flaps have been turned down, it is often quite easy to see or define the position of the uterine arteries. A curved needle, threaded with silk, is passed beneath the artery on either side and securely tied. Forceps are applied above the ligatures, and the artery may be divided between them and the ligature. If the artery has not been properly secured, it spurts at once, but can be easily seized with forceps, and tied. The opposite uterine artery is tied in a similar manner. Some operators expose the artery by dissecting down on to it through the peritoneum, and ligaturing it at once.

The main vessels are now secured, and the tumour is cut away at the level of the peritoneal flaps. Small vessels on the surface of the stump may need ligature. This is best done by passing a buried suture beneath the bleeding spot and tying it tightly. The peritoneal cavity is cleared of all blood, and any further oozing controlled.

The flaps are now approximated over the cut surface of the stump, and the divided edges of the broad ligament closed. This may be done with a continuous fine silk ligature.

In this way the whole of the operation field is enclosed and covered with peritoneum, and the pedicle is allowed to drop into the pelvis.

All instruments and gauze sponges are counted, and the abdomen closed in the usual way.

By the intra-peritoneal methods very good results are obtained, there is less risk of septic absorption or of subsequent ventral

hernia, and the convalescence is similar to that of an ordinary ovariectomy.

HOWARD KELLY'S MODIFICATION OF PARTIAL HYSTERECTOMY.

—In this method of removing fibroid uteri, instead of tying and dividing the broad ligaments on either side *before* severing the pedicle, the operator works across the pelvis from one side to the other; one broad ligament is divided, then the pedicle is cut across from side to side, the tumour being turned upwards. The other broad ligament is then tied. Peritoneal flaps are made, as in the operation for partial hysterectomy. The uterine arteries are tied before division, or, if not, they are seized with clamps and tied, as the incision is made across the cervix. The wound area is then covered with the peritoneal flaps, as described above.

FIG. 191. — Hysterectomy. Large pressure forceps for applying to broad ligament close to uterus, to control hæmorrhage.

Fibroids involving the cervix sometimes lead to difficulty in removal, as they expand the cervical portion and become jammed in the pelvis. In such cases the operation consists in first ligaturing the uterine vessels, as described above, and then shelling the tumour out of its capsule, consisting of the lower portion of the expanded cervix. This is now closed with sutures, and the peritoneum sewn over it. It is better not to attempt complete removal of the cervix in such cases, as the

ureters may be injured and the bleeding difficult to arrest.

Some of the most difficult operations in connection with fibroids are those in which large cervical or subserous tumours burrow beneath the layers of the broad ligaments. In other cases they grow beneath the peritoneum, either in the front of

the abdomen or posteriorly. They are very perplexing, as their anatomical relations to the uterus and other structures are very varied. Many have to be treated by enucleation, as described above, for sessile ovarian tumours. Fibroids sometimes originate in the round ligament of the uterus, or in the ovary.

(c) COMPLETE HYSTERECTOMY (PAN-HYSTERECTOMY).—In this operation the whole uterus is taken away by the abdominal route, and no stump is left. It may be undertaken for malignant disease of the body of the uterus, where the tumour does not admit of removal by the vagina, and when the position of a fibroid tumour does not permit of division through the cervix.

Operation.—This is similar to that for partial hysterectomy, but after ligation of the uterine arteries the vagina is opened from above. The relations of the vagina are carefully determined; an assistant may, if necessary, introduce his hand or a pair of long forceps into the vagina as the incision is being made.

It is preferable to open the vagina first posteriorly. Then, after determining the position of the bladder, the anterior fornix is cut into. The lateral attachments are now clamped and tied, and the remaining tissues cut through close to the cervix.

The vagina is then closed with sutures, and the peritoneal flaps and cut edges of the broad ligaments approximated by a continuous suture.

Some operators in performing pan-hysterectomy prefer to separate the cervix first through the vagina, ligaturing the

FIG. 192.—Myoma screw.—DOYEN.

lowest portions of the broad ligaments, and opening the anterior and posterior peritoneal pouches. The abdomen is then opened, and the operation completed from above.

Separating the cervix first in this way greatly facilitates the later stages of the abdominal part of the operation, as the vagina is already opened, and the bleeding, which is often very troublesome at this stage, is controlled.

Abdominal myomectomy.—This operation has only a limited application, but has yielded good results in the hands of some operators.

It consists in the removal of one or more pedunculated fibroids by abdominal section, preserving the uterus, ovaries, and Fallopian tubes. The tumours are removed from their uterine connections by transfixing and ligaturing their pedicle.

Abdominal enucleation.—This consists in shelling the tumour out of the uterine walls, and then closing the wound in the uterus.

This method may also be employed in removing fibroids which burrow in the broad ligaments, but in such cases it is often impossible to save the uterus.

Abdominal hysterotomy.—This consists in the removal of a submucous fibroid, by an incision through the walls of the uterus. After removal, the wound is closed, as in Cæsarean section. It is very rarely performed.

MISCELLANEOUS OPERATIONS ON THE UTERUS AND UTERINE APPENDAGES.

Ventral fixation of the uterus—hysteropexy.—The operation consists in opening the abdomen and stitching the uterus to the abdominal wall. It is useful in some cases of prolapse and retroflexion of the uterus.

Special instruments.—Beyond those needed for an ordinary abdominal section, blunt volsellum forceps and some large curved needles are necessary.

Position.—The patient is placed in the Trendelenberg position.

Operation.—The abdomen is opened by a short median incision in the hypogastric region. The recti muscles are separated, and the peritoneum stripped off from their under surface for about an inch on either side. The uterus is now felt for, and raised up to the abdominal incision, if possible by the fingers, as even blunt volsellum forceps are liable to tear the uterus. A large curved needle, threaded with silkworm-gut, is passed through the fundus of the uterus from side to side, entering

near one Fallopian tube and emerging near the opposite one. Each end of the suture is now passed through the abdominal muscles on either side and through the skin. Two similar stitches, one above and the other below the first, are also inserted. These also pass through the muscles of the abdominal wall, but not the skin. Next, the peritoneum above and below these stitches is closed with fine silk.

The fundus is thus held in apposition to the muscles of the abdominal wall (not to peritoneum). The three uterine stitches are now tied, and those involving the muscles cut short; the other closes the wound over the fundus. The rest of the incision is closed by a few sutures, if necessary. Ventral fixation of the uterus is not always followed by good results, and, in women who are not past the menopause, difficulties are said to ensue should the patient become pregnant.

Shortening the round ligaments (Alexander's operation).

—In this operation the round ligaments are exposed in each inguinal canal. These are pulled upon, shortened, and then stitched to the pillars of the external abdominal ring. The operation cures retroflexion, but it does not cure prolapse. It is not often performed in this country.

Cæsarean section. — In this operation the fœtus and placenta are removed from the uterus by abdominal section. Cæsarean section is performed for extreme degrees of pelvic contraction and for solid tumours of the pelvis or uterus, which obstruct labour. Cancer of the cervix, certain cicatricial conditions of the passages, and osteo-malacia may also necessitate operation. The indications for Cæsarean section are of two kinds, absolute and relative. Absolute indications are conditions which make delivery in any other way impossible. The relative indications are conditions in which it is possible to deliver in other ways, but it is judged that Cæsarean section is the best, though not the only way.

When there is no hope of obtaining a living child *per vias naturales*, even by the induction of premature labour, then it is reasonable to expose the mother to risk to save the life of the child. It should in many cases replace the operation of craniotomy. Cæsarean section also offers the great advantage that the patient can be sterilised at the time if necessary, especially if the conditions causing obstruction are permanent ones.

The operation may be performed at a pre-arranged time before labour, or labour pains may be induced by the passage of a bougie. Lastly, Cæsarean section may be an emergency operation on a woman already in labour. It is best to fix a

definite time for the operation, and to have the patient properly prepared.

Instruments.—The instruments are those used in ovariectomy.

Position.—The patient is arranged as for abdominal section. A special assistant is told off to look after the child.

Operation.—The incision through the abdominal wall should be 5 or 6 in. long, beginning in the middle line near the umbilicus, but it should not be extended too far down into the pubic region. The bladder limits should be carefully defined. It is well not to cut too deeply at first, as the abdominal walls are often very thin, and the uterus may be wounded at this stage. The uterus is centred, the abdominal wound is hooked upwards by the finger, and an incision is made through the uterine wall at its upper portion, *i.e.*, in the *upper* uterine segment. When the foetal membranes are reached, the wound is rapidly enlarged upwards and downwards. It is best not to cut into the lower uterine segment; this can be determined by the loose attachment of the peritoneum to the lower portion of the uterus. The uterine incision should be at least 6 in. long; if the placenta lies beneath the incision, it may be cut through. Bleeding at this period of the operation is generally free. The membranes being ruptured, the child is extracted as rapidly as possible by grasping a knee. The umbilical cord is clamped or tied, and the child handed to the care of the special assistant. The uterus should now contract, and may be brought out of the wound and held by the other assistant, while the placenta and membranes are removed. The interior of the uterus may be swabbed out with 1 in 1000 sublimate solution. The uterus now contracts further, and much of the bleeding will stop, though it will not finally stop till the wound is sutured. Kneading the uterus, or surrounding it with hot gauze sponges, will aid its contraction.

The uterine sutures.—These are deep and superficial. Silk-worm gut, silk or silver, may be used. The deep sutures include the muscular layers, but *not* the mucosa; as a rule, ten or twelve deep stitches are sufficient. The superficial sutures are passed through the peritoneum only, on each side, after the manner of Lembert. Good peritoneal apposition is very important.

Very little difficulty is met with in closing the uterine incision, as long as this only occupies the contractile upper uterine segment. If the lower segment is cut into, great care should be taken to close the incision in this region very accurately, as leaking of blood beneath the loose peritoneum may give rise to a considerable hæmatoma.

If the condition requiring Cæsarean section is one that is permanent, the patient should be sterilised, in order that she should not (unless she desires it) run the risk of a subsequent pregnancy. Sterilisation is generally performed by ligature and resection of a portion of each of the tubes, though even this has failed in preventing subsequent conception. The ovaries should not be removed, unless for the cure of osteo-malacia. The abdominal wound is closed in the usual way.

Porro's operation.—This consists in Cæsarean section followed by amputation of the body of the uterus and its appendages, the uterine stump being fixed in the lower angle of the wound, as described in the extra-peritoneal method of abdominal hysterectomy for fibroids. The abdomen having been opened, a piece of rubber tubing is passed over the top of the fundus uteri and adjusted round the neck. The ends of the tube are now tightened, knotted, and the knot grasped by forceps, to prevent slipping. The uterus is cut into, and the child extracted. The uterus is now lifted out of the abdomen, and the ligature round its neck again tightened. In this way no hæmorrhage takes place.

Two Porro's pins, or two knitting needles, are passed through the cervix from side to side, either through or immediately above the rubber tube. The pins prevent the ligature from slipping upwards. The body of the uterus is then amputated about an inch above the pins and ligature.

The stump is stitched into the lower angle of the wound, which is then closed in the usual way. The lowest suture for closing the abdominal wound may also include the stump, and thus shut off the peritoneum.

The stump, pins, and elastic ligature, which are now extra-peritoneal, are carefully dressed till the slough separates.

Much better results are now obtained, after removal of the uterus, by treating the stump by the intra-peritoneal method already described.

Operations for extra-uterine gestation.—These may be considered briefly—(a) Before rupture has taken place ; (b) at the time of rupture ; (c) after rupture.

(a) **OPERATION BEFORE RUPTURE OF THE TUBE.**—The question of operation depends upon diagnosis ; but if it be suspected that a tubal pregnancy exists, operation should be undertaken at once. No good can come of delay. The operation is similar to that for removal of the uterine appendages. The abdomen is opened in the middle line, and the relations of the sac determined ; both tubes should be examined. The tubal sac is then

drawn up into the wound, clamped with forceps, and the pedicle transfixed and ligatured.

(b) AT THE TIME OF RUPTURE.—This includes cases of primary rupture of the tube and tubal abortion. Rupture may take place into the peritoneal cavity, or into the broad ligament. Tubal abortion is associated with the formation of a tubal mole (hæmorrhage into the foetal membranes). The mole may be expelled into the abdominal cavity, or may hang from the open mouth of the Fallopian tube. In such cases a pelvic hæmatocele results. The bleeding, however, is less severe than in primary rupture of the tube, and not all cases demand operation. In cases of primary rupture, when the symptoms are so grave that life is threatened, there can be no doubt as to the advisability of operation. In cases of rupture into the broad ligament, it is justifiable to wait, as the hæmatoma is limited, and can, if necessity arise, be dealt with later by drainage.

Operation for primary rupture.—This, in serious cases, yields the most brilliant results of any operation in surgery. The abdomen is opened in the middle line, and as the peritoneum is divided, free blood may at once escape, or the whole belly may be filled with dark clots. The clots are turned out, and the fundus uteri and affected tube sought for. The sac is drawn out of the wound, clamped, and ligatured, as in removal of the appendages. All bleeding must be stopped before the abdomen is closed. If necessary, the peritoneum may be washed out with warm sterilised salt solution, a quantity of which may be left in, and the abdomen closed in the usual way.

(c) AFTER RUPTURE.—In most cases the fœtus is destroyed after rupture of the sac, whether this be into the peritoneum or between the layers of the broad ligament.

As a rule, the blood effusions (pelvic hæmatocele and pelvic hæmatoma) remain quiescent, or are absorbed, and no operation is required. Should, however, repeated bleeding take place, with recurrent attacks of pain and anæmia, abdominal section should be undertaken, and the tube removed. The operation is often very difficult, on account of the adhesions to bowel and omentum. Such cases may necessitate drainage for a few days.

RUPTURES INTO THE BROAD LIGAMENT.—If abdominal section is necessary, the sac can sometimes be opened without entering the general peritoneal cavity at all; if not, the edges of the sac wall are stitched to the skin incision, and the cavity drained after the removal of the embryo, clot, and placenta.

A suppurating hæmatocele, bulging into Douglas's pouch, may be incised and drained by the vagina.

IF THE FÆTUS SURVIVES.—In these cases, the dangers of operation increase as the pregnancy advances. No good seems to come of expectant treatment. In such operations, the great difficulty is that of the treatment of the placenta. If separated at the time, hæmorrhage is sure to occur, and if the placenta is left *in situ* there is the risk of septic absorption. In performing abdominal section, if possible the sac should be opened extra-peritoneally. The child is then extracted, and the cord clamped. If the sac can be removed, so much the better, but this is not often possible. Failing this, the sac is stitched to the edges of the abdominal wound, and drained. The placenta may be left to come away by itself, keeping the sac open by free drainage with gauze.

When the fœtus is dead, the operative risks are very much less, as the placental circulation has probably ceased. In such cases, removal of the placenta may be possible. The distortion and displacement of the peritoneum by a pregnancy growing between the layers of the broad ligament is most puzzling, and the anatomical relations of such sacs must carefully be determined at the time of operation. For further details on the operative treatment of extra-uterine pregnancy, special works on the subject may be consulted.

OPERATIONS UPON THE LARYNX.

Laryngotomy.—The term “laryngotomy” is used to designate an operation which consists in establishing a communication between the interior of the larynx and the surface of the neck, through an incision dividing the crico-thyroid membrane.

(a) *Indications*.—Sudden impaction of a foreign body, such as a portion of food or a tooth-plate, in the upper aperture of the larynx.

(b) Some forms of disease of the upper part of the larynx, such as cedema due to swallowing hot fluids, in which the obstruction is only temporary.

(c) As a preliminary measure in some operations on the mouth, tongue, and larynx.

Laryngotomy is usually an operation of emergency, since diseases of slow progress are rarely confined to the upper portion of the larynx.

Special instruments.—Blunt hooks, tracheal dilator, and laryngotomy tube.

Position.—The patient is placed in the dorsal posture, with a hard pillow underneath the neck, and the head projecting slightly over the end of the table; the surgeon stands on the right side of the patient, and his assistant directly opposite to him. If available, another assistant stands at the patient's head, and steadies it, so that the chin, prominence of the thyroid cartilage, and suprasternal notch are maintained in a straight line.

Usually it will not be possible to give the patient an anæsthetic,

FIG. 193.—Laryngotomy. Position of patient, and line of incision.

owing to the urgency of the case, and the imperative need for immediate operation.

Operation.—With the finger and thumb of the left hand the surgeon grasps the larynx and holds it firmly, then he makes a vertical incision in the middle line of the neck, about an inch in length, commencing, above, just below the notch of the thyroid cartilage, and extending downwards to the lower border of the cricoid. This incision divides the skin, superficial and deep fasciæ, and exposes the interval between the two sterno-hyoid muscles. These muscles are held aside with blunt hooks, and the lower border of the thyroid cartilage defined. The anterior surface of the crico-thyroid membrane will then be visible. It is cleared as far as the cricoid, when an incision half an inch in length is made through it and the underlying mucons membrane,

along the upper border of the cricoid, and at right angles to the direction of the external incision. This having been done, the cavity of the larynx is opened, and the dilator introduced, and not till then should the surgeon's left finger and thumb be removed from its grasp on the larynx. The laryngotomy tube is then introduced, and fixed in position by tapes. If the wound has been made rather long, the extremities are approximated by the insertion of a few points of suture.

: During the course of the operation all bleeding vessels are immediately seized with pressure forceps. The transverse cut in the crico-thyroid membrane is to avoid the anastomosis of the crico-thyroid arteries—branches of the superior thyroid.

FIG. 194. — Laryngotomy tube.

Thyrotomy.—The operation of thyrotomy consists in the division of the thyroid cartilage through an incision in the middle line of the neck.

Indications.—(a) Some forms of disease of the larynx, in which it is impossible for the surgeon to make an exact diagnosis, such as suspected epithelioma.

(b) The presence of foreign bodies within the sacculus laryngis, or the interior of the larynx, which cannot be extracted by other measures.

(c) Papillomatous growths of the vocal cords, which cannot be satisfactorily removed by the intra-laryngeal method.

(d) Some forms of ulceration of the inter-arytenoid region of the larynx (malignant and tuberculous), which are considered suitable for local removal.

Special instruments.—Sharp hooks, Volkmann's spoon, small saw (Hey's), and ligature material (silk and silver wire), and the instruments for tracheotomy.

Preliminary tracheotomy.—Three or four days before the performance of thyrotomy, it is advisable to perform a preliminary tracheotomy, or this can be done as the first stage of the operation. In either case a sponge should be packed around the upper portion of the tracheotomy tube, so as to prevent the passage of blood and particles of growth into the trachea.

Position.—The patient is placed in the dorsal posture, with the neck supported by a sandbag or a pillow, and near the end

of the operation table. The operator stands on the right side of the patient, and the assistant opposite to him on the left.

Operation.—The operation should be carried out in four stages—

(a) *External incision.*—The thyroid cartilage is fixed between the thumb and forefinger of the left hand, and a vertical incision, in the middle line of the neck, is commenced about half an inch below the body of the hyoid bone, and extended downwards to the upper border or the middle of the cricoid cartilage.

This incision divides the skin and fasciæ, and defines the interval between the two sterno-hyoid muscles. These muscles are separated with retractors, and the fascia in front of the thyroid cartilage divided.

(b) *Division of thyroid cartilage and opening of laryngeal cavity.*—If the patient is under 40, it is usually possible to divide the thyroid cartilage with a scalpel along the middle line from the centre of the notch above to the cricothyroid membrane below, but in older people this cartilage becomes ossified, and it is necessary to use a small saw for its division. Before the cartilage is divided, it is well to pass a silk ligature through both alæ. The

FIG. 195.—Thyrotomy. External incision.

cartilage having been cut through, this ligature is pulled out of the larynx, and cut across. The two halves of the ligature then serve as retractors to draw aside either half of the cartilage. If a ligature is not used, the two halves are drawn apart with retractors or sharp hooks. The lateral alæ having been separated by one of the above methods, the mucous membrane which appears at the bottom of the wound is divided so as to open up the interior of the larynx. When this has been done, and the two halves of the thyroid further separated, the interior of the larynx will be fully exposed to view. It is advisable at this stage to plug the upper part of the trachea with a small sponge, attached to a piece of silk passed downwards between the vocal cords (if it has not already been done). If, however, the rima glottidis is much encroached upon by new growth, this procedure is not possible.

(c) *Removal of diseased tissue, or foreign body.*—If the operation has been performed for the removal of a papillomatous growth, this is removed either by scraping with a Volkmann's spoon, or by careful cutting with a fine pair of scissors or a scalpel; or if for a localised epithelioma, this is dissected away, care being taken to cut through normal tissue well beyond the margins of the affection. In the case of ulceration, in tuberculosis of the larynx, the affected areas are well scraped, so as to remove all affected tissue. When a foreign body is lodged in the sacculus laryngis, it is extracted, if possible, through the opening of this space into the cavity of the larynx; or, if this cannot be done, the mucous membrane over the most prominent point of the impacted body is incised, and then the extraction is performed.

In order to render the mucous membrane in the interior of the larynx more tolerable to surgical interference, and hence prevent reflex coughing, it is recommended that the entire laryngeal mucous membrane be painted with a 20 per cent. solution of cocaine before the operation is commenced.

If any arteries are cut across during the performance of the intra-laryngeal part of the operation, they are picked up with fine artery forceps, and ligatured in the usual manner.

(d) *Closure of the external wound.*—When all bleeding has been arrested, the incision in the mucous membrane which corresponds to that in the thyroid cartilage is closed with a continuous silk suture. Next, the two halves of the thyroid cartilage are brought together and fixed in apposition with one or two sutures of silver wire. The holes made by the silk ligature afford a valuable indication in obtaining exact apposition. Finally, the wound in the fasciæ and skin is closed by the insertion of several points of interrupted suture of silk or silkworm gut.

After-treatment.—The tracheotomy tube is worn for several days after the operation. When the swelling of the mucous membrane of the larynx has subsided, the tube is removed, and the wound allowed to close by granulation. The tracheotomy tube can usually be removed at the end of a week.

Excision of the larynx, or laryngectomy.—Excision of the larynx may be either complete or partial. In the former case the entire organ is removed with all its cartilages, and in the latter only the portion involved in the disease, usually a lateral half, is taken away.

Indications.—Removal of the larynx is only carried out for primary malignant disease, which does not involve the adjacent structures to any considerable extent.

Special instruments.—Sharp hooks, periosteal elevator, sponge-holders, tampon cannula, sponge plugs.

Preliminary tracheotomy.—Before attempting removal of the larynx, complete or partial, ten days or a fortnight previous to the operation a preliminary tracheotomy should be performed. It is advisable to open the trachea below the isthmus of the thyroid gland—low tracheotomy—if possible, so that the tracheotomy tube will not be in the way during the operation, and sufficient room will be allowed for plugging the trachea above the tube.

Position.—The patient is placed lying upon the back near the right edge of the table. The shoulders are slightly raised, and a hard pillow placed underneath the neck. The operator stands on the right side of the patient and his assistant on the left.

Operation.—Removal of entire larynx.—The positions of the hyoid bone, the thyroid cartilage, and cricoid cartilage are first defined. An incision is then made in the middle line of the neck, commencing at the lower border of the hyoid bone and extending downwards to a short distance below the cricoid. This incision divides the skin and fasciæ and exposes the surfaces of the cricoid and thyroid cartilages and the crico-thyroid and thyro-hyoid membranes in the interval between the two sterno-hyoid muscles. A transverse incision is next made along the inferior margin of the body and great cornua of the hyoid bone. When the hyoid bone is exposed, the attachments of the sterno-hyoid, anterior belly of the omo-hyoid, and anterior portion of the thyro-hyoid muscle are divided, and the anterior aspect of the thyro-hyoid membrane fully laid bare. If the anterior margins of the sterno-mastoid muscles overlap the lateral portions of the larynx, they are pulled aside with retractors, but not divided.

The thyroid cartilage is split anteriorly, the interior of the laryngeal cavity examined, and the extent and connections of the disease defined. If the entire organ, including the epiglottis, is found to be diseased, the operation is continued as follows:—

The attachments of the thyro-hyoid and the sterno-thyroid muscles to the external surface of the thyroid cartilage are separated with a periosteal elevator, and all the soft structures on the outside of the larynx peeled back. As the posterior part of the larynx is being reached, the attachment of the inferior constrictor muscle of the pharynx is separated from the cricoid and thyroid cartilages. As this is being done, the crico-

thyroid branches of the superior thyroid arteries will require ligature, together with any small muscular branches which may be met with. Next, the superior laryngeal branches of the superior thyroid arteries are secured, just before they pass through the thyro-hyoid membrane. Then the thyroid cartilage is pulled forward by an assistant, by means of sharp hooks, whilst the surgeon cuts through the median and lateral portion of the thyroid-hyoid membrane immediately below its attachment to the body and great cornua of the hyoid bone.

The epiglottis can now be hooked forwards, whilst the mucous membrane along its margins is incised, care being taken that the cut is made well beyond the disease. By careful dissection from above downwards, after the mucous membrane above the arytenoid cartilages has been cut through, and by gentle traction the entire larynx can be pulled forwards, and its separation from the pharynx effected. Care must be taken not to button-hole the œsophageal or pharyngeal wall in the region of the cricoid cartilage. When the separation has been carried beyond the limits of the disease, the crico-tracheal membrane, or one of the upper rings of the trachea, is cut through transversely and the larynx removed. As this is being done, the margins of the trachea must be secured by passing two or more strong silk sutures through its wall; otherwise, it may retract downwards towards the thorax.

All bleeding points are ligatured, and the sutures which pass the tracheal wall tied to the margins of the lower part of the external wound.

The upper portion of the wound is sponged out, and the margins of the incision in the pharyngeal wall approximated by the insertion of sutures.

The sponge-plugs are removed from the trachea, the tracheotomy tube taken out, and a cannula passed into the trachea from its upper end.

The entire wound is next packed with tampons of aseptic absorbent gauze. Usually it is advisable to unite the transverse portion of the incision with sutures, but the vertical portion should be allowed to close by granulation.

After-treatment.—The wound is kept as clean as possible by daily dressing and sponging. The patient is fed by means of an œsophageal tube until the wound has commenced to close up.

When the external wound has sufficiently healed, the patient is fitted up with an artificial larynx, to enable him to articulate. Fig. 196 is a representation of an instrument which is used for this purpose.

Removal of part of the larynx.—The early stages of the operation are similar to those for complete excision.

A vertical incision is made down to the cartilages, and the soft tissues drawn well aside. Next, the thyroid cartilage is split in a vertical direction, and the interior of the laryngeal cavity examined. If the disease is found to be strictly confined to one-half of the organ, unilateral extirpation may be carried out.

The transverse cut along the lower border of the hyoid bone is made on the affected side, and the soft parts detached and peeled backwards as in complete excision.

It is not generally necessary in partial excision to remove

FIG. 196.—Excision of the larynx: Gussenbauer's artificial larynx.

A. External view.

B. Section.

any part of the cricoid cartilage. If the epiglottis is diseased, it will be necessary to split it in a vertical direction, and to remove the affected half along with the corresponding portion of the thyroid cartilage. If it is not necessary to do this, the line of separation is made along the aryteno-epiglottidean fold of the diseased side.

Intubation of the larynx.—Intubation of the larynx is a bloodless operation, which has been introduced to replace tracheotomy in favourable cases. The operation is carried out by passing a metal tube into the laryngeal canal through the mouth; the enlarged upper end of the tube, when it has been introduced, rests upon the vocal cords, and the lower extremity extends downwards into the trachea.

Indications.—(a) Some forms of œdema of the larynx in which the stenosis is likely to be temporary.

(b) Stenosis of the larynx due to laryngeal croup.

(c) Chronic stenoses of the larynx which are fibrous in character, and due to the contraction of scar tissue formed as the result of previous inflammation and ulceration.

Special instruments.—A set of O'Dwyer's tubes, a mouth-gag,

FIG. 197.—Intubation Instruments.

a. Extubator.

b. Intubator.

c. Gag.

d. Intubation tube and pilot.

e. Pilot.

f. Guage.

a tube introducer or intubator, an extubator, and a long piece of silk of moderate thickness.

Position.—The patient (if a child) is placed in the sitting position on the knee of a nurse, a towel being wrapped around the chest so as to enclose the arms. The assistant fixes the head with his hands, and holds the mouth open with the gag. The surgeon stands or sits directly in front of the patient.

Operation.—The mouth of the child is held open by the gag (Fig. 197, c) which is introduced and held in position by the

assistant. A tube of suitable size is selected, the corresponding pilot is fixed on the intubator, the tube itself passed over the pilot, and a piece of silk passed through the aperture in the margin of the flange. Next, the surgeon passes his left forefinger into the child's mouth and hooks forwards the epiglottis. The intubator and tube are taken in the right hand, and the introduction of the tube is accomplished by passing it along the left forefinger until the upper aperture of the larynx is reached. The free extremity of the tube is pushed downwards, until the flange at the upper part rests upon the vocal cords, and the distal end reaches the upper part of the trachea. The tube is then detached from the intubator and the latter withdrawn. The piece of silk attached to the tube is fixed to the temporal region of the patient with a strip of strapping.

When it is wished to remove the tube, the child is held in the same position as before, and the distal end of the extubator (Fig. 197, *a*) is passed into the upper aperture of the tube. The latter can then be removed.

OPERATIONS UPON THE TRACHEA.

Tracheotomy.—In the operation of tracheotomy an artificial communication is made between the interior of the trachea and the surface of that part of the neck between the lower border of the cricoid cartilage and the episternal notch.

The cervical portion of the trachea consists of about eight rings, commences above at the lower border of the cricoid cartilage, and terminates below at the level of the episternal notch. The relations of the trachea to the surrounding structures are shown in Fig. 198.

The isthmus of the thyroid gland usually crosses the front of the trachea, opposite the second and third and occasionally the fourth rings. When the opening into the trachea is made above the isthmus of the thyroid gland, the operation is called "high" tracheotomy; and when below, the "low" operation. The former is the one which is the more commonly performed, since it is less dangerous and is more easily carried out.

Operation of "high" tracheotomy. — *Indications.* — The operation of tracheotomy may be required in the following clinical conditions, namely—

(*a*) Certain cases of laryngeal diphtheria.

(*b*) Some forms of chronic ulceration of the larynx, where respiration is dangerously interfered with, or it is wished to

give rest to the diseased areas, such as tuberculous, syphilitic, and epitheliomatous ulcerations.

(c) Cases of severe stenosis of the larynx dependent upon cicatrization, or when the interior is filled up with proliferating growths, such as papillomata.

(d) For the removal of foreign bodies in the lower portion of the trachea, or the bronchi.

(e) As a preliminary to the performance of some severe operations about the upper part of the pharynx, mouth, or nose.

Special instruments.—Blunt hooks, two-bladed tracheotomy dilator, tracheotomy tube and tapes.

Position.—The patient is placed in the dorsal position, with the head projecting slightly beyond the end of the operation table (Fig. 199). A sandbag is placed underneath the neck.

The operator stands on the right side of the neck of the patient, the chief assistant opposite to him, and the anæsthetist (if an anæsthetic is being given) at the head. The anæsthetist will act as a second assistant, if occasion demands.

Operation.—The operation may be divided into three stages, namely—

(a) *External incision.*—The head of the patient is so placed that the symphysis of the lower jaw, the prominence of the thyroid cartilage, and the episternal notch, are in a straight line corresponding to the middle line of the whole body; and all through the operation this position of the head is maintained by the anæsthetist. If the head is allowed to deviate to one or other side, the operation is made more difficult, especially in young children. The cricoid cartilage is next defined, and grasped between the thumb and forefinger of the left hand, which grasp is not relaxed till the dilators are introduced into the trachea. The central point of the cricoid cartilage is taken, and an incision made vertically downwards from this point for $1\frac{1}{2}$ in., towards the centre of the episternal notch. In an adult with a fat neck, it is necessary to make the incision longer.

FIG. 199.—Tracheotomy. Position of patient, and line of incision in “high” operation.

With the scalpel, the skin, superficial fascia, and anterior layer of the deep fascia are divided, and the space between the muscles opened. This space is lozenge-shaped, being limited externally by the sterno-hyoid muscles above, and by the sterno-thyroids below. The fascia in this interval is incised, and the muscles drawn aside with retractors or blunt hooks by an assistant. The pre-tracheal layer of the cervical fascia is next divided, and the anterior aspect of the upper rings of the trachea and the isthmus of the thyroid gland laid bare.

(b) *Exposure and incision of the trachea.*—The isthmus of the thyroid gland is drawn downwards with a blunt hook, so as to fully expose the upper two or three tracheal rings. In order to facilitate this, it is sometimes advisable to divide the fascia transversely, immediately below the lower border of the cricoid. When the surface of the trachea has been thoroughly exposed,

an incision is made with the scalpel, its edge directed towards the cricoid cartilage through its upper three rings, and also through the crico-tracheal membrane, in the middle line and in an upward direction. During all these manipulations the cricoid cartilage and the upper rings of the trachea have been steadied in position by the left forefinger and thumb of the surgeon.

If any blood vessels (usually veins) are divided during the early stages of the operation, they are picked up with artery or pressure forceps by the assistant, and ligatured.

(c) *Introduction of the tracheotomy tube, and partial closure of the external wound.*—When an opening has been made into the cavity of the trachea, its presence is made evident by the rushing sound which is produced by the entrance of air. The margins of the incision in the trachea are held apart by passing into it dilators or a pair of dressing forceps, the blades of which are afterwards separated. All diphtheritic membrane or other loose substance is allowed to be coughed out from the trachea, and then the tube is inserted. The tube is threaded with tapes, and then inserted into the tracheal aperture between the blades of the dilator. The dilator is now withdrawn, and the tube fixed by tying the tapes around the neck.

If the external wound is large, the portions above and below the tube are united by the insertion of one or two points of suture. Dress-

FIG. 200. — Tracheotomy.
Tracheal dilators.

ings are applied, and the patient sent back to bed.

Operation of "low" tracheotomy.—This operation is occasionally necessary in severe dyspnoea, dependent upon compression of the trachea by an enlarged thyroid gland, or by malignant enlargement of the lymphatic glands of the neck. It is performed as a preliminary operation in laryngectomy, and also for foreign bodies impacted in the bronchi.

The operation only differs from the "high" operation in the position of the external incision, and the greater depth to which the dissection has to be carried. The incision is usually 3 in. in length, or even more; it commences below the cricoid cartilage, and extends to the upper border of the episternal notch. The same muscles are separated, the thyroid isthmus is pulled upwards instead of downwards, whilst the inferior thyroid veins and the thyroidea ima artery (when present) have to be dealt with.

In young children, if this operation has to be performed, the point of the scalpel must not be allowed to extend into the thorax behind the manubrium sterni, otherwise the innominate artery, the left innominate vein, or the arch of the aorta, may be injured. The upper portion of the thymus gland may cover this part of the trachea and require to be drawn aside.

Laryngo - tracheotomy. —

In young children it is often advisable to incise both the cricoid cartilage and the upper rings of the trachea, in order to give sufficient room for the easy introduction of a tracheotomy tube. The operation is similar to the ordinary operation of "high" tracheotomy, with the exception that the incision in the neck extends to a slightly higher level, and the cricoid cartilage is divided at the same time as the upper rings of the trachea. In this operation, one, or at most two, rings of the trachea require division.

FIG. 201.—Tracheotomy. Tracheotomy tube.—PARKER.

OPERATION UPON THE LUNGS.

Pneumotomy.—By the term "pneumotomy" is understood that surgical operation which has for its object the making of an incision into the lung.

Indications.—(a) Localised abscess of the lung.

(b) Gangrene of the lung.

(c) Hydatid cyst of the lung.

(d) Foreign bodies within the lung which are giving rise to symptoms, and are so situated that they are capable of removal.

(e) Bronchiectasis, when the cavities are of considerable size, and increasing.

(f) Some forms of tuberculous cavity of the lung, especially when single, and not associated with tuberculous disease elsewhere.

Special instruments.—Periosteal elevator, aneurysm needles, trocar and cannula, drainage tube.

Position.—When the exact position of the affected portion of the lung has been defined, the patient is placed lying somewhat on the sound side, and with the affected side near or partially projecting beyond the edge of the operation table. The surgeon stands on the affected side of the patient, and the assistant opposite to him.

Operation.—The position of the abscess, cyst, etc., is made out, an exploring syringe being used if necessary. An incision is made over the middle of the affected area, and so situated that it is parallel with the underlying intercostal space or rib.

This incision will usually be from 3 to 4 in. in length. It is deepened until the external intercostal muscle is exposed. If the space laid bare is wide enough for the proposed treatment, the intercostal muscles are divided in the line of the original incision, care being taken to keep near the lower border of the space, so as to avoid injury to the intercostal vessels; the parietal pleura covered by the endothoracic fascia is then exposed. If the parietal and visceral layers of the pleura are adherent at this point, an incision is made into the lung tissue, until the cavity or cyst is reached. The cavity may be opened by first pushing inwards the needle of the exploring syringe, and then passing the blades of a pair of dressing forceps along the needle.

When the lung is not adherent to the chest wall, the pleural cavity is opened by incising the parietal pleura. Contamination of the pleural cavity must be avoided, either by stitching the lung and visceral pleura to the opening in the parietal pleura, or by packing with tampons of aseptic gauze. In some cases it may be advisable to attempt to obliterate the cavity by inducing the formation of adhesions between the visceral and parietal layers of the pleura.

When the intercostal space is small, a portion of one or more ribs should be resected (see p. 489).

The cavity of the abscess or cyst having been opened, the contents are allowed to exude. In the case of a hydatid cyst, the margins of the incision in the cyst should be stitched to those of the parietal incision, and drainage established; and in

the treatment of abscesses or gangrenous cavities, after the contents have been removed a drainage tube should be inserted. This tube should be of soft rubber, and not too long, otherwise it may cause laceration of the lung tissue forming the boundaries of the cavity, and give rise to hæmorrhage.

OPERATIONS UPON THE PLEURA.

Paracentesis thoracis, or thoracentesis.—This operation has for its object the removal of pus, pleural fluid, or other fluid collection from the interior of the thoracic cavity, usually from within the pleura.

Indications.—(a) Collections of fluid within one or other

FIG. 202.—Paracentesis thoracis. Aspirator, with vacuum bottle and exhausting syringe.

pleural cavity, which in most instances are either serous or purulent. The diagnosis of these conditions is not always possible without exploratory puncture with a needle or an aspirating syringe.

(b) Hydatid or other cysts of the lung, and localised abscesses of the lung, as an aid to their diagnosis, and in order to facilitate the performance of a surgical operation.

Special instrument.—Aspirator or exploring syringe.

Position.—The patient is placed lying somewhat on the sound side, with the affected part of the chest near the edge of the bed. The surgeon seats himself behind the patient, opposite the part of the thoracic wall it is proposed to aspirate. A general anæsthetic is not necessary, but the local application of cocaine may be advantageous.

Operation.—The exact locality of the fluid collection within the chest having been defined, a very small incision is made through the skin over one of the intercostal spaces. It is usual to select a space directly over the central part of the fluid collection. The thumb-nail of the left hand is pressed against the superior margin of the rib which forms the inferior boundary of the selected space, a small notch in the skin is made with the scalpel, and then the exploring needle, or the needle of the aspirator, is pushed inwards until the underlying cavity is reached. Care must be taken to push the needle well into the fluid-containing space, but not beyond this, otherwise either the lungs or some other structure will be damaged. Often the pleura bounding the fluid-containing space is much thickened by the deposition of layers of fibrin, which may be a slight obstacle

FIG. 203. — Incision of pleura. Position of patient, and line of external incision, in incision of pleura, with resection of a portion of rib.

to the needle passing into the cavity. When the needle has entered the cavity, a condition which can generally be recognised by the sense of diminished resistance at the point of the instrument, it is connected with the aspirator or syringe, which should have been already exhausted.

The fluid collection is allowed to flow out slowly, in order to avoid, if possible, the occurrence of syncope, an accident which may happen.

During the entire procedure the strictest aseptic precautions must be observed, otherwise a non-purulent collection of fluid may be converted into a purulent one, owing to the entrance of septic micro-organisms with the needle.

Serous collections within the pleural cavity can usually be cured by this operation, but when we have to deal with an empyema it is nearly always necessary to provide a freer exit for the pus, and to establish drainage. This is done according to the method described in the next operation.

Incision of the pleura.—An incision is generally made, either through the sixth intercostal space in the mid-axillary line, or through the eighth or ninth intercostal space in the scapular line.

Position.—As for aspiration.

Special instruments.—Sequestrum forceps, grooved steel director, periosteal elevator, saw or bone forceps.

Operation.—The intercostal space, which it is proposed to incise, having been decided upon, an incision is made, $1\frac{1}{2}$ to 2 in. in length, over the middle of the space, and parallel with the rib (Fig. 203). The skin, fasciæ, and overlying muscles are incised until the external intercostal muscle is exposed. The steel director is then pushed inwards through the intercostal muscles and the parietal layer of the pleura, until its point is felt to enter the cavity. Then the blades of a pair of dressing forceps or sequester forceps are passed along the groove in the director, and separated, the director being removed when the forceps have been introduced. The pus or fluid will then exude from the opening thus made, and the cavity be emptied.

When all the fluid has been removed, a moderately large drainage tube is inserted and fastened in position, and antiseptic dressings applied.

In children and in patients who have narrow intercostal spaces, it is often necessary to resect a portion of one rib in order to establish satisfactory drainage. When this is the case, an incision is made down to the external surface of the rib, and the periosteum divided for the length of the incision. With a periosteal elevator, the periosteum is separated from the rib, and then the bone is divided with bone forceps or a small saw.

A portion of rib—usually $1\frac{1}{2}$ in. is sufficient—having been removed, the pleural cavity is opened with a director and dressing forceps as above.

After-treatment.—The dressings should be removed daily, and the tube taken out, and, after the first few days, gradually shortened and replaced by one of smaller calibre.

Excision of part of the bony wall of an empyema cavity (Estlander's operation)—thoracoplasty.—Removal of a considerable portion of the bony chest wall is necessary in those

FIG. 204. — T-shaped drainage tube, for drainage of pleura. It is made out of two pieces of rubber tubing, the vertical limb being passed through a slit in the transverse one. The cuff prevents slipping of the tubes.

cases of long-standing empyema in which the cavity does not spontaneously close.

Operation.—The limits of the cavity which it is proposed to close having been ascertained as far as possible by percussion, auscultation, and examination with probes or sounds, a semi-lunar flap, comprising all the soft tissues of the chest wall superficial to the ribs, is reflected, the attached base of the flap being in most cases above (Fig. 205). In raising the muscles from the ribs, care must be taken that no periosteum is raised with it. It is safer, in fact, to leave a small portion of the muscle attached to the rib. All bleeding having been arrested

FIG. 205.—Excision of part of chest wall.

a. External incision.

by the application of pressure forceps, portions of the exposed ribs are removed. The amount of each which is excised depends entirely on the size of the cavity which it is proposed to close; often it is necessary to remove portions of four, five, or six ribs, pieces from 2 to 5 in. long being taken from each. The longest portions of rib are taken from over the middle of the empyema cavity.

After portions of the ribs have been removed and the cavity thoroughly exposed, it will usually be found advisable to take away the thickened part of the parietal pleura which forms the external boundary of the cavity. In order to do this satisfactorily, it will be necessary to ligature some of the intercostal arteries along the anterior and posterior

margins of the exposed space.

When the cavity has been laid thoroughly open in this manner, its interior is well washed out, all traces of pus and lymph being removed, if necessary, by scraping with a Volkmann's spoon.

The entire cavity is then packed with strips of antiseptic gauze, one extremity of each strip protruding from the lower part of the wound. This having been done, the external flap of soft tissues is replaced and fixed in its former position by the insertion of a number of interrupted sutures. The lower part, however, is left open for the exit of the extremities of the tampons of gauze. Finally, an absorbent antiseptic dressing is applied.

After-treatment.—At the expiration of from twenty-four to forty-eight hours, the gauze packing is removed from the interior of the chest, the cavity syringed out with an antiseptic solution, and then packed as before. This is repeated periodically, until the wound is healed.

Some surgeons advise that, instead of making a large “U-shaped” flap of soft tissues, a separate incision should be made over each rib of which a portion is to be removed. In my opinion, however, the above operation is more satisfactory, since it enables a complete examination of the interior of the cavity to be made, and allows the removal of thickened pleura and the layers of fibrous lymph which are usually met with.

CHAPTER XII.

OPERATIONS UPON THE PERICARDIUM AND HEART.

PARACENTESIS PERICARDII.

INCISION OF PERICARDIUM.

TREATMENT OF WOUNDS OF PERICARDIUM AND HEART.

Paracentesis pericardii.—This operation consists in withdrawing, by means of an aspirating trocar and cannula, collections of fluid from the pericardial cavity.

Indications.—(a) As a means of diagnosis in some cases of distension of the pericardium.

(b) For the withdrawal of a serous effusion of the pericardium which is not amenable to ordinary medical treatment, and in which the amount of fluid is increasing.

Special instruments.—Aspirating trocar and cannula.

Position.—The position of the patient will depend upon his condition; usually it will be more convenient to perform the operation with the patient sitting up. The operator sits on the bed, on the left side of and opposite to the patient.

Operation.—A point is selected over the fifth left interspace, either outside the line of the internal mammary artery—that is to say, about 1 in. from the margin of the sternum—or on the inner side of this vessel, close to the lateral margin of the sternum.

A small incision is made in the skin with the scalpel, and the trocar and cannula carefully pushed inwards until the pericardial cavity is reached; this is recognised by the sense of diminished resistance to their passage. The trocar is withdrawn, and the cannula connected with the vacuum, and the contained fluid evacuated.

When the cavity has been emptied, the cannula is taken out and the aperture covered by a small aseptic dressing.

If the fluid within the pericardium is found to be purulent,

aspiration is not sufficient, but incision and drainage must be performed.

Incision of the pericardium.—*Indications.*—Purulent pericarditis, and wounds of the heart.

Position.—As for the preceding operation.

Operation.—An incision 1 in. to $1\frac{1}{2}$ in. long is made over the fifth left intercostal space, parallel with the costal cartilages, commencing at the outer margin of the sternum.

The skin, fasciæ, pectoralis major, and intercostal muscles are divided, care being taken to avoid the internal mammary artery. This blood vessel lies at right angles to the incision, and at about half an inch from the lateral margin of the sternum. A steel director is then pushed inwards until the pericardial cavity is reached, and then through the pericardium; this may be known by the exit of the pus along its grooved surface. The blades of the dressing forceps are passed along the groove of the director, and separated, the director being removed. By this means free exit is given to the pus.

If the contained pus is very offensive, it may be desirable to irrigate the pericardial cavity.

All the pus having been removed, a soft rubber drainage tube is passed into the cavity, and dressings of aseptic gauze applied.

Treatment of wounds of the heart and pericardium.—

Indications.—The indication for the adoption of surgical treatment in this connection is direct local evidence of injury to the heart or pericardium, associated with immediate and continued enlargement of the cardiac dulness and embarrassment of the heart's action; or the diagnosis, from these symptoms, of the extension of some remote or indirect injury to this vicinity.

Special instruments.—Periosteal elevator, bone forceps, Hey's saw, "lion" forceps.

Position.—The position must depend on the patient's condition, who, if necessary, must be allowed to sit up, well supported behind. The surgeon stands where most convenient to himself under the circumstances. A local or general anæsthetic may be administered.

Operation.—The proceedings may be carried out in the following stages:—

(a) *Skin incision and reflection of flaps.*—A vertical incision is made 2 in. to the left of the left border of the sternum, from the lower border of the fourth rib to the lower border of the sixth. Transverse incisions are made at the extremities of

this and at right angles to it, and the resulting flaps reflected, on the one side up to the outer border of the sternum, and on the other side for some 2 or 3 in.

(b) *Resection of thoracic wall.*—At the outer limits of the area thus exposed the fifth and sixth ribs are cut through with bone forceps, their muscular and fascial connections with the ribs above and below secured and together turned inwards, the costal cartilages being divided if necessary.

(c) *Examination of pericardium.*—Any blood clot or fluid is now sponged away, and if necessary the left pleura retracted outwards. Should a wound in the pericardium be found, it may then be sutured. Should further examination be deemed necessary, this wound is enlarged and the pericardial cavity exposed; or, if no wound be visible, the pericardium may be incised.

(d) *Treatment of pericardial cavity, and suture of heart and pericardium.*—The pericardial cavity is then sponged clean, and any wound on this aspect of the heart united with interrupted sutures of catgut, passing through heart muscles but avoiding its cavity.

The wound in the pericardium is then sutured, the edges being well everted.

(e) *Closure of external wound.*—The resected portion of the thoracic wall may then be replaced and sutured in position, and the skin incision closed.

CHAPTER XIII.

OPERATIONS UPON THE ŒSOPHAGUS.

ŒSOPHAGOTOMY, OR INCISION OF THE ŒSOPHAGUS.

ŒSOPHAGOSTOMY.

ŒSOPHAGECTOMY, OR EXCISION OF A PORTION OF THE ŒSOPHAGUS.

REMOVAL OF A POUCH OF THE ŒSOPHAGUS.

Œsophagotomy.—Œsophagotomy, or the making of an incision into the œsophagus, is usually carried out through an incision placed in the inferior part of the left anterior triangle of the neck.

The œsophagus is a continuation downwards of the pharynx. It commences opposite the middle of the cricoid cartilage, at the level of the upper part of the sixth cervical vertebræ, or the disc between the fifth and sixth, and terminates immediately below the œsophageal opening in the diaphragm.

The cervical portion of the tube is the part upon which the operation of œsophagotomy is generally performed; but the œsophagus may be exposed as it lies within the thorax, through an incision on the left side of the spinal column, after portions of two or more ribs have been resected.

The cervical operation will be described.

Indications.—(a) Impaction of a foreign body, such as a tooth-plate, in the œsophagus; (b) some forms of fibrous stricture occurring high up in the œsophagus, and which cannot be dilated by means of œsophageal bougies passed through the mouth; (c) pedunculated fibrous tumours of the œsophagus, which project internally.

Special instruments.—Long-bladed forceps and œsophageal bougies.

Position.—The patient lies in the dorsal position, with a sandbag underneath the neck. The head is turned towards the right side. The surgeon stands on the left side of the patient's neck, and his assistant on the right.

Operation.—The operation of œsophagotomy may be carried out in the following stages, namely—

(a) *External incision.*—An incision from 3 to 4 in. in length is made along the anterior border of the left sterno-mastoid muscle, commencing at the sternal extremity of the left clavicle, and extending upwards as far as the upper border of the thyroid cartilage. This incision divides the skin, superficial fascia and platysma, and the deep fascia, and exposes the external surface and anterior border of the sterno-mastoid muscle.

(b) *Exposure of œsophagus.*—The anterior border of the sterno-mastoid muscle is well defined, and the structure retracted to the outer side, by which means the infra-hyoid group of muscles will be laid bare. The anterior jugular vein will usually be met with at this stage, and should either be drawn aside or ligatured. The layer of deep cervical fascia which lies behind the sterno-mastoid is incised, so as to fully expose the infra-hyoid group of muscles. The intermediate tendon of the omohyoid is cut through, and the infra-hyoid group of muscles retracted towards the inner side.

In the floor of the incision, the left lateral lobe of the thyroid gland, covered by fascia, is seen internally, and the carotid sheath with its contents externally. The fascia which covers the thyroid gland is divided; the gland is drawn inwards, and the carotid sheath outwards. The deep fascia which is exposed at the bottom of the wound is incised in the line of the original incision, and the above-mentioned structures further retracted. The inferior thyroid artery will now be laid bare in the lower part of the wound. It is surrounded with ligatures in two places, and divided between. In the bottom of the wound the anterior aspect of the longus colli muscle will be seen, and on the inner side the œsophagus, which can be recognised by its red colour.

The recurrent laryngeal nerve of the left side must be carefully avoided; it lies in the chink between the trachea and the œsophagus. It can be pulled to the inner side with a blunt hook.

(c) *Incision of the œsophagus, removal of the foreign body, or dilatation of the stricture.*—When the foreign body is impacted in the exposed portion of the œsophagus, an incision should be made through the wall of the tube in a longitudinal direction, and the obstruction removed with long-bladed forceps. If the impacted body is situated at a lower level, but can be readily felt, an œsophageal bougie is passed down the œsophagus, and a

cut made on to it in a longitudinal direction. The bougie is then withdrawn, and the margins of this incision are held apart with retractors, and long-bladed forceps passed downwards, and an attempt made to extract the impacted body.

In the case of fibrous stricture, a bougie is passed downwards until the upper limit of the stricture is reached; a longitudinal cut is made as above, and then the stricture is carefully divided from within by means of a long, narrow-bladed, straight bistoury.

When the operation is being performed for the removal of a pedunculated non-malignant tumour, the location of the swelling is established by palpation. Then a longitudinal incision through the œsophageal wall is made directly over the tumour, and its pedicle is surrounded by a silk ligature, and the tumour removed by cutting across the pedicle distal to the ligature.

(d) *Further treatment of the wound.*—If possible, the aperture in the œsophageal wall should be closed by the insertion of interrupted sutures of fine silk or catgut, one tier uniting the mucous membrane, and a second one the muscular wall. If this can be done satisfactorily, the external incision is closed in the usual manner, except at one extremity, where a small drainage tube or a strip of antiseptic gauze is introduced and passed down to the wound in the œsophagus. If the incision in the œsophageal wall cannot be thoroughly closed, or if there has been ulceration, or the tube is in a septic condition, no attempt is made to close the aperture; the entire wound in these cases is packed with pads of antiseptic gauze.

Œsophagostomy.—If it is wished to keep open the incision in the neck, the margins of the aperture in the œsophagus are stitched to those of the external wound, a soft rubber tube is passed into the œsophagus, and the remainder of the incision is packed with gauze. The patient is fed through the rubber tube. This operation is generally known as œsophagostomy.

Œsophagectomy.—Œsophagectomy, or removal of a portion of the œsophagus, has been attempted by a number of surgeons. The success, however, which has followed these operations has been very small, and on this account a description of the operation is not given.

Removal of a pouch or diverticulum of the œsophagus.—During the past few years a small number of operations have been successfully carried out for the extirpation of a localised pouch or diverticulum of the cervical portion of the œsophagus.

Operation.—The position of the pouch or diverticulum, as regards the side of and the structures in the neck, are first made

out, and also the seat of the opening into or connection with the lumen of the œsophagus. An incision 4 in. long is made along the anterior margin of the lower portion of the sterno-mastoid muscle on the affected side of the neck. In most instances the pouch is located on the left side. The superficial tissues are divided and the sterno-mastoid muscle retracted outwards, and if necessary the sternal portion divided in the lower angle of the wound. The deep cervical fascia is divided for the entire length of the incision, and the infra-laryngeal muscles retracted outwards, or cut through if necessary. The structures in the carotid sheath are also retracted outwards, and the lateral lobe of the thyroid gland upwards. By these procedures the surface of the sac will become exposed in the bottom of the wound. By careful dissection it is separated from its surroundings, and the neck or communication with the œsophagus made out. When this is apparent, it is transfixed and tied close to the œsophagus, and the distal portion removed by cutting with scissors. When there is a somewhat wide neck, it may be necessary to transfix and ligature it in several places. The pouch having been removed, the bottom of the wound is thoroughly sponged clean, and then the opening into the œsophagus further closed with sutures. Usually it will be found advisable to insert three tiers of sutures—one for the mucous membrane, the second for the muscular layer, and a third for the surrounding fibrous layer. Catgut of medium thickness is the best suture material for the purpose.

A gauze drain should now be passed down to the region of the sutured portion of the œsophagus, and brought out through one angle of the external wound. The remaining portion of the external wound is closed by sutures in the usual manner.

CHAPTER XIV.

OPERATIONS UPON THE THYROID GLAND.

EXTIRPATION OF ONE LOBE.

ENUCLEATION OF ENCAPSULED TUMOURS (CYSTS AND ADENOMATA).

Extirpation of one lobe.—Unilateral extirpation of the thyroid gland is usually carried out through an incision along the anterior border of the sterno-mastoid muscle of the affected side. Kocher often employs a transverse or curved incision.

Indications.—(a) Bilateral bronchoceles (parenchymatous goitres) which do not yield to medicinal treatment, and which are growing and causing serious dyspnœa owing to pressure upon the trachea.

(b) Multiple cysts or adenomata of one-half of the gland.

(c) Some forms of malignant disease of the thyroid gland, when the surrounding structures are not infiltrated. When the disease has spread to the adjacent tissues, it is not advisable to attempt removal, owing to the important structures which are involved.

Position.—The patient lies in the dorsal position, with the head turned towards the sound side, the neck being supported by a hard pillow or sandbag. The operator stands on the affected side of the neck, and his assistant directly opposite to him.

Operation.—Removal of one-half of the thyroid gland may be divided into the following stages:—

(a) *External incision.*—An incision from 3 to 8 or 10 in. in length, according to the size of the lobe to be removed, is made over the prominent part of the swelling, and usually in a line from the sternal extremity of the clavicle to the mastoid process. This incision divides the skin, superficial fascia, platysma, and the anterior jugular vein or one of its tributaries. The external jugular vein may be exposed at the upper end of the incision, and should be drawn aside. These veins lie underneath the platysma, but in the superficial fascia,

(b) *Division or retraction of infra-hyoid muscles, and exposure of the thyroid gland.*—The deep fascia which has been laid bare in the first incision is divided for the entire length of the wound, and the anterior border of the sterno-mastoid muscle exposed. This is pulled outwards with retractors. The infra-hyoid muscles (sterno-hyoid, sterno-thyroid, and omo-hyoid) are now seen lying spread out upon the gland. They must be carefully divided or retracted. In the case of large goitres, they frequently lie in deep grooves in the gland. The enlarged lobe of the thyroid will now be apparent.

The sheath or capsule of the thyroid gland will now be exposed, and running in this sheath numerous veins will be visible. Incision of this sheath must be carefully avoided,

or serious and perhaps uncontrollable hæmorrhage may occur.

FIG. 206.—Excision of thyroid gland.

a. Line of first incision for removal of left lobe.

(c) *Isolation of the lobe, ligation of the thyroid vessels, and division of the isthmus.*—The superior thyroid artery and vein, and the middle and inferior thyroid veins, are now carefully isolated, tied with double ligatures, and divided. The lateral lobe of the gland is now lifted forwards and inwards. Special attention must at this point be paid to the breathing, which is apt to become seriously em-

barrassed if there is much pressure upon the trachea.

Any prolongation of the enlarged gland behind the pharynx, trachea, or œsophagus is dealt with during this stage.

The swelling must now be separated from its connections with the lateral portion of the larynx, the operator dissecting from above downwards. The isthmus is now met with, attaching the gland to the anterior aspect of the trachea, and the lateral lobe of the opposite side. With blunt instruments the isthmus is separated from the trachea, and then clamped or tied. The isthmus is then divided on the proximal (or tumour) side of the ligatures, and the separation of the tumour continued. When the isthmus is very large, it is better to cut it across and tie the blood vessels separately. If necessary, pressure forceps are placed on the blood vessels of the tumour. The dissection is

prolonged downwards until the inferior limits of the tumour are reached; in this stage it is occasionally necessary, when the lateral lobe of the thyroid extends to the upper aperture of the thorax, to expose the dome of the pleura, the subclavian artery, and the large veins.

When the thyroid gland has been separated from all these connections, the inferior thyroid artery and accompanying veins will usually be readily found entering the posterior and inner aspect of the gland, on a level with the upper rings of the trachea. Great care should be taken to avoid injuring the recurrent laryngeal nerve, which, by the side of the trachea, lies in very close relation to the artery. The main artery may be tied outside the nerves, or the separate branches may be tied on the inner side of the nerve and just before they enter the gland.

(d) *Removal of the lobe, and closure of external wound.*—The inferior thyroid vessels having been ligatured, they are cut, the enlarged lobe is lifted upwards, and any fascial connections which still remain undetached are divided, and the tumour removed. The bottom of the wound is sponged dry, and all bleeding points picked up with artery forceps, and carefully ligatured. Care must be taken in so doing that too much tissue is not taken up with the blood vessels, otherwise branches of the sympathetic cord, or the recurrent laryngeal nerve itself, may be surrounded by the ligature.

All bleeding having been most carefully arrested, the divided infra-hyoid muscles may be reunited by buried sutures, and the external incision is then closed by the insertion of a row of salmon-gut sutures.

The inferior extremity of the wound should be left open, and a drainage tube of glass or soft rubber, or a strip of aseptic gauze introduced. This is usually necessary on account of the large size and great depth of the wound, and of the difficulty of applying sufficient pressure without causing interference with respiration.

Dry aseptic dressings are applied, and held in position by bandages, which are made to include also the head and shoulders.

The chief dangers in the removal of thyroid tumours are the occurrence of serious hæmorrhage, and the division or ligature of nerves. These, however, can be avoided by attention to the precautions given above.

If, during the course of the operation, the breathing becomes very much embarrassed, owing to pressure of the tumour on the

trachea, it may occasionally be necessary to perform tracheotomy. This should, however, be avoided, if possible, since, when tracheotomy has been performed, the wound in the neck, in nearly all instances, becomes infected with septic micro-organisms. This usually results in suppuration, which is very prone to extend to the mediastinum, and cause a fatal termination.

Removal of the entire thyroid gland is rarely, if ever, necessary, on account of the complications which occur after such an operation. The mental condition of the patient is seriously affected, and the patient suffers from a kind of myxœdema.

Enucleation of encapsuled tumours (cysts and adenomata).—When cysts and adenomatous tumours of the thyroid gland only involve a part of the affected lobe, it is preferable to attempt a local removal in place of extirpation of one-half of the gland.

Special instruments.—As for removal of a lateral lobe ; a blunt thyroid scoop is often useful.

Position.—As for preceding operation.

Operation.—An incision is made over the most prominent portion of the swelling. The incision is deepened until the external aspect of the affected portion of the gland is exposed. There is invariably a layer of gland tissue lying in front of the tumour ; this may be thick, and resemble normal gland tissue, or it may be thin, and look like fascia. This must be divided, and the surface of the cyst or adenoma laid bare.

The glandular capsule of the cyst or tumour having been divided, the localised swelling is separated from its bed with a director, finger, a thyroid scoop, or other blunt instrument, and removed. In some cases of cystic swelling, removal will be much facilitated by incision of the cyst wall, and evacuation of the contents. During and immediately after the enucleation, there is often profuse hæmorrhage, which must be stopped by forceps, by pressure of sponges, and by eversion of the wound, so as to give easy access to the deeper parts of the cavity. The external wound is closed by sutures except at one extremity, where a drainage tube or strip of gauze is brought out.

In some few cystic swellings it will be found impossible to effect a local removal, on account of the vascularity of the walls and the absence of a distinct fibrous tissue capsule. Extirpation of one-half of the thyroid gland must then be effected. In very rare cases of cysts fixed by old inflammation, it may be better to be content with mere drainage, carried out after incision of the cyst wall, evacuation of the contents, and stitching of the margins of the incision in the cyst to those of the parietal

wound. Cysts so treated, however, are prone to suppurate, a condition which is to be avoided, if possible.

Enucleation of very large tumours may be attended with a dangerous amount of hæmorrhage. In these cases, it is generally best to perform resection-enucleation, in which the size of the wound in the gland is greatly reduced.

CHAPTER XV.

OPERATIONS UPON THE TONGUE.

EXCISION OF THE ENTIRE ORGAN—

1. Through the mouth.
2. Through an incision in the neck.
3. With division of the cheek, and resection of the lower jaw.

REMOVAL OF A PORTION OF THE TONGUE—

1. One lateral half.
2. A "wedge-shaped portion."

REMOVAL of the tongue, either partial or complete, may be carried out through the oral aperture, through an incision in the submaxillary or submental regions, or after division of the cheek and resection of a portion of the lower jaw on one side. Before carrying out an extensive operation upon the tongue and the adjacent parts, it is advisable, and in many cases necessary, to perform a preliminary laryngotomy, and then to plug the upper portion of the pharynx with a sponge, or to use a Hahn's or Trendelenberg's tracheotomy or laryngotomy tube (Figs. 207 and 208). In place of special forms of tubes, in my opinion it is quite as convenient to use a marine sponge of suitable size, encircled with a strong silk ligature, for plugging the cavity of the upper part of the pharynx. This proceeding prevents the passage of blood into the trachea, facilitates the administration of the anæsthetic, and also enables the anæsthetist to keep well out of the way of the operator and his assistant. The introduction of an ordinary laryngotomy tube does not cause so much injury to the larynx as when either Hahn's or Trendelenberg's tubes are used (Figs. 207 and 208).

Indications.—(a) Carcinoma of the tongue which admits of complete local removal, and in which there is not too extensive involvement of lymphatic glands by secondary growths. It may be considered advisable in some cases to remove the disease within the mouth, although there are numerous and extensive

secondary growths, in order to diminish the likelihood of the occurrence of inhalation septic pneumonia, and to make the patient's condition somewhat more comfortable. Removal of *one lateral half* of the tongue should only be recommended in those cases in which the malignant disease is absolutely confined to the half it is proposed to remove, and there is no sign of extension to the fibrous median septum. Removal of a "*wedge-shaped piece*" is only permissible when the disease is of quite recent development, and is entirely limited to the lateral margin of the tongue.

An attempt should be made in all cases to remove the cervical lymphatic glands which receive the lymphatic vessels from the portion of the tongue which is involved in the disease. When the lingual artery is ligatured through a submaxillary incision, in order to control possible hæmorrhage, the lymphatic glands should be removed at the same time. Great care is requisite in removing these glands,

FIG. 207.—Hahn's tracheotomy tube, with sponge sheath.

FIG. 208.—Trendelenberg's tracheotomy tube, with rubber sheath.

as they lie in close relation to the sub-maxillary salivary gland, and one or more are prone to escape observation. When any doubt exists as to whether all of these submaxillary lymphatic glands have been removed or not, it is better to remove the submaxillary salivary gland as well.

(b) Sarcoma of the tongue which admits of local removal, and is not associated with the presence of internal secondary growths.

(c) Nævus of the tongue.

(d) Lymphangioma of the tongue.

The latter two classes of patients provide the most suitable cases for removal of localised portions of the tongue.

Excision of the entire tongue.—THROUGH THE MOUTH.—Excision of the entire tongue through the mouth is the more usual operation which is practised for carcinoma, since this method allows of complete removal of the diseased organ, and does not leave a visible scar. It ought to be borne in mind, however, when deciding upon the adoption of this method, that in all cases where malignant disease (carcinoma) has been present for some time, the lymphatic glands which receive the lymphatic vessels from the affected portion of the tongue are extremely likely to be the seat of carcinomatous elements, which sooner or later will become apparent as secondary growths. In some instances the lymphatic vessels themselves appear to have been the seat of these cells or elements, and secondary growths have commenced in them. Usually, however, the carcinomatous elements are carried direct to the lymphatic glands in the neck, and are not arrested in the course of the lymphatic vessels. The reason of this is not clear, but it is undoubtedly a clinical fact. This is the opposite to what occurs in connection with the lymphatic vessels of the mammary gland, where they pass through the pectoralis major muscle.

Preliminary ligature of the lingual artery.—Preliminary ligature of the lingual artery is advisable in most of these operations—first, because the operation upon the tongue can be carried out with very little loss of blood; and, secondly, because it allows the submaxillary lymphatic glands to be removed at the same time. When the carcinomatous growth of the tongue is in a septic and foul condition, it is better not to ligature the lingual artery in the neck at the time of removal of the tongue, but at a later period to remove the submaxillary lymphatic glands by a second operation. In septic cases of this kind, suppuration in the cervical wound is liable to happen, which may cause serious consequences, such as cellulitis in the fascial planes of the neck, and secondary hæmorrhage from the lingual artery.

The operation of removal of the tongue through the oral aperture by means of scissors, is often referred to as Whitehead's operation.

Special instruments.—Strong straight blunt-pointed scissors, gag, large needle, sponge-holders.

Position.—The patient is placed in the dorsal posture near one edge of the table, with the head somewhat raised and turned towards the operator. The surgeon stands on the side of the most affected part of the tongue, one assistant stands at the head of the patient, and a second opposite the surgeon.

Operation.—The gag is introduced on the least affected side, and held firmly open by the assistant at the head. A strong ligature is passed through the anterior portion of the tongue, at the junction of the anterior with the middle third. This is left long, and serves as a retractor to pull the tongue forwards. The tongue is drawn forwards and upwards towards the roof of the

FIG. 209.—Excision of tongue. Gag for keeping the jaws separated.—ACKLAND.

mouth, whilst the mucous membrane of the floor of the mouth and the anterior pillars of the fauces is divided. This will enable the surgeon to pull the greater part of the tongue out of the mouth, and hence give a better view of the parts which are being operated upon.

The soft parts of the tongue are divided, well beyond the limits of the growth, by a series of short snips with the scissors from without inwards to the middle line. One or two small arteries will be cut, and when they spurt they are picked up with pressure forceps and ligatured. The lingual arteries, when they have not been ligatured in the neck, are looked for in the anterior part of the incision, on each side of the middle line, and nearer the inferior surface of the organ than the dorsum. When they are seen they are seized with pressure forceps, and divided

on the distal side. Next, the remainder of the tongue is boldly cut through with the scissors, and the entire organ removed. Care must be taken to carry the incision well beyond the limits of the disease. The lingual arteries are ligatured, and then the cut surface of the base of the tongue is sponged, and any other bleeding points sought for, and tied. The base of the tongue may be hooked forwards by passing the index finger into the upper part of the pharynx, and exerting forward traction. This proceeding is of considerable value in the temporary arrest of hæmorrhage from the lingual arteries, if they have been divided before being seized with pressure forceps. The vessels are compressed against the posterior aspect of the lower jaw.

Before the operation is finished, a loop of strong silk should be passed through the stump of the tongue. This is brought out through the mouth, and fixed to the cheek with a piece of strapping. It will serve to control hæmorrhage if it occur.

When all the hæmorrhage from the base of the tongue and the floor of the mouth has been arrested, the incised surfaces are sponged dry, dusted with iodoform, and the operation is completed.

Excision of the tongue after splitting the cheek and division or resection of a portion of the lower jaw.—This operation is especially applicable in those cases of carcinoma of the tongue which extend backwards and infiltrate the region of the fauces, the floor of the outer portion of the buccal cavity, and the adjacent part of the lower jaw. This method of operation gives very free exposure of the diseased areas, and enables the surgeon to take away all the infiltrated tissues. Some surgeons object to the operation on account of the deformity which results, and also to what they say is an increased mortality owing to the development of septic processes in the neck. As regards the first objection, this has been very much over-rated, since, if care be taken to carefully suture the divided portions of the cheek together, little if any visible deformity results. Concerning the increased mortality from septic causes, this has not been my experience, provided each patient is well looked after for the first week, so as to avoid any accumulation of septic discharges.

Special instruments.—Mouth gag, saw, bone forceps, tooth forceps.

Position.—The patient is placed in the dorsal position, with a firm sandbag underneath the shoulders, and the head turned towards the sound side. The operator stands on the affected side of the patient and the assistant opposite to him.

Operation.—Usually it will be found advisable to perform a preliminary laryngotomy, and to plug the pharynx with a marine sponge.

The operation can be most conveniently divided into the following five stages:—

(a) *Skin incision and splitting the cheek.*—The assistant grasps the cheek on the affected side so as to control the circulation, and then the surgeon makes an incision which commences at the angle of the mouth (Fig. 210), extends horizontally backwards to the anterior margin of the masseter, downwards parallel to the anterior margin of this muscle as far as the inferior margin of the horizontal ramus of the lower jaw, and then onwards to the anterior margin of the sterno-mastoid muscle in the sub-maxillary region, whence it is curved inwards, forwards, and upwards for about 1 in. in the direction of the symphysis menti. This incision is made to divide all the tissues of the cheek, and to expose the lower jaw and the anterior margin of the sterno-mastoid muscle. In the outer part of the incision over the ramus of the jaw, or on the anterior margin of the masseter, the facial artery will be divided and will require ligature. Other vessels requiring ligature are the coronary

FIG. 210.—a. Line of incision for removal of tongue, after splitting cheek and dividing lower jaw.

arteries in the region of the angle of the mouth. The flap of cheek and tissues of the neck is next dissected downwards and forwards, so as to fully expose the horizontal ramus of the lower jaw and the structures in the submaxillary triangle.

(b) *Division or resection of a portion of the lower jaw.*—When it is not necessary to remove a portion of the lower jaw, on account of its freedom from disease, it is sawn through immediately behind the last molar tooth. The anterior segment is then drawn forwards and towards the opposite side, whilst the other part is pulled forcibly outwards and backwards. By these means the lateral aspect of the tongue, the floor of the mouth, and the region of the fauces are laid bare. When, however, a portion of the jaw is involved in the disease, the limits

of the infiltrated bone are exactly defined, the tooth at each extremity of the affected portion removed, and then with a small saw the ramus of the jaw is sawn through in front of and behind the region of the infiltrated portion. Great care must be taken to make the section of the bone wide of the disease. When the bone has been sawn through, the separated portion is removed and the two segments pulled aside, so as to give a full exposure of the interior of the buccal cavity and the extent of the disease.

(c) *Removal of tongue.*—This having been done, the mucous membrane of the floor of the mouth is cut through a short distance from the margins of the diseased area, the pillars of the fauces divided, if necessary, and the tongue cut through well behind the infiltrated or ulcerated portions. When only one-half of the tongue is involved, the mucous membrane should be divided along the middle line on the dorsal and ventral aspects, and the organ split backwards into two halves. These cutting operations can be most easily done with strong curved scissors. In cutting through the substance of the tongue, especial care should be taken, when the ventral aspect is being reached, to discover the position of the lingual arteries, and, when seen, these should be seized with pressure forceps before section. The sublingual glands can generally be removed at the same time as the tongue.

(d) *Removal of the submaxillary salivary and lymphatic glands.*—When the tongue has been removed, the region of the submaxillary triangle should be investigated, and the submaxillary salivary and lymphatic glands removed. It is desirable also, in cases of extensive disease, to investigate the vertical chain of lymphatic glands along the anterior border and deep aspect of the sterno-mastoid, and if any of these are enlarged, they ought to be dissected free from their surroundings and taken away.

(e) *Closure of external wound.*—If possible, the margins of the mucous membrane on the dorsum of the stump of the tongue should be approximated to the cut margins of the mucous membrane of the floor of the mouth by a few sutures. This tends to prevent falling back of the stump of the tongue over the upper aperture of the larynx, and facilitates healing. In those cases in which the lower jaw has been divided, and no portion taken away, the two fragments are brought into apposition, drilled with some form of bone perforator, and then fixed in close connection by the insertion of a suture of silver wire. When, however, a segment of bone has been removed, after all

haemorrhage has been arrested, the cavity of the wound is packed with strips of antiseptic gauze. Finally, the margins of the wound are fixed close together by the insertion of a series of interrupted silkworm-gut sutures. Especial care should be taken to secure exact coaptation in the region of the angle of the mouth. The lowest and most dependent portion of the wound should be left unsutured, and through it either a strip of antiseptic gauze or a drainage tube brought out.

When the operation has been completed, the laryngotomy tube is removed, and the external incision closed by a few points of suture. Before removing the tube, care must be taken to remove the sponge-plug from the upper portion of the pharynx, and to sponge all the air-passage free of blood clot.

After-treatment.—The gauze packing should be left in for about twenty-four hours, and then removed. The entire wound should be frequently syringed out with an antiseptic solution, and great care taken to ensure free exit and early removal of all discharges which may collect.

Excision of the tongue through an incision in the sub-maxillary region (Kocher's operation).

Special instruments.—Mouth gag and sponge-holders.

Position.—The patient is placed in the dorsal position, with the head supported by a pillow, and turned to the sound or least affected side. The surgeon stands on the affected side and his assistant directly opposite to him.

Operation.—The operation can be conveniently divided into three stages:—

(a) *External incision, exposure and removal of enlarged lymphatic glands and submaxillary salivary gland.*—An incision is made, commencing a short distance below and in front of the apex of the mastoid process, extending downwards and forwards to the upper border of the great cornu of the hyoid bone, then inwards to the middle line of the neck, and finally upwards to the lower part of the symphysis menti. This incision divides the skin, superficial fascia, platysma, superficial veins, and the deep

FIG. 211.—Excision of tongue (Kocher).
External incision.

fascia,—all these structures being reflected upwards in the form of a flap. By this means the superficial portion of the submaxillary salivary gland and the enlarged anterior cervical and submaxillary lymphatic glands are exposed; the lymphatic glands are separated and pulled upwards with a retractor, together with the submaxillary salivary gland. The facial artery, as it lies in a deep groove in the gland, is sought for and ligatured in the lower part of the wound. Next, the lingual artery as it passes underneath the hyoglossus muscle, is defined and ligatured. In the upper part of the incision the mylo-hyoid muscle will be laid bare, and in the lower part the two bellies of the digastric and the stylo-hyoid muscles will be visible.

(b) *Division of floor of mouth; isolation and removal of tongue.*—On the deep aspect of the mylo-hyoid is the mucous membrane of the floor of the mouth. Both these structures are perforated, and the aperture enlarged, when the cavity of the mouth and the side of the tongue will be fully exposed. The tongue is brought through the aperture in the floor of the mouth, and the mucous membrane around it divided with scissors, and then almost the entire organ, together with the growth, can be brought out. This having been done, the tongue is detached by cutting through its attachment to the hyoid bone. Care must be taken to secure the lingual artery of the opposite side as soon as it is reached.

(c) *Treatment of external wound.*—The tongue having been removed, all bleeding points are ligatured, and part of the external wound closed by the insertion of simple interrupted sutures. The most dependent part is left open. The wound is packed with antiseptic gauze, the extremity of the strip being brought out through the external wound.

After-treatment.—The wound is dressed at first twice daily; later, once is sufficient. Feeding is carried out through an œsophageal or nasal tube, if requisite.

Excision of a portion of the tongue.—Excision of a portion of the tongue may comprise remove of one lateral half, removal of a wedge-shaped portion, and removal of a localised piece from a lateral half.

Excision of half the tongue.—The performance of this operation is indicated in those cases of carcinoma of the tongue in which the disease is absolutely limited to one lateral half, and has not extended to the fibrous tissue which forms the median septum. The operation may be carried out either through the oral aperture, through a submaxillary incision, or after section of the cheek and division or removal of a portion of the lower jaw, as in the class of cases mentioned in connection with removal of the entire organ. Excision of half the tongue through the oral aperture is indicated when the disease is limited to the diseased half of the tongue, and has not extended to the floor of the mouth and the adjacent tissues, so as to cause extensive infiltration. When the disease mainly involves the lower aspect and outer margin of the tongue, and has extended thence to the adjacent portions of the floor of the mouth and the lower jaw, it is better to split the cheek and remove the

portion of lower jaw which is involved, before attempting to deal with the tongue itself. When the jaw is uninvolved, and the floor of the mouth and the underlying tissues are the chief seat of infiltration, the submaxillary operation should be selected.

Excision of one-half of the tongue through the mouth.—The lingual artery of the affected side may be tied in the usual manner, and the submaxillary lymphatic glands removed in those cases in which the mouth and diseased portion of the tongue are in a comparatively clean condition. When the malignant growth is in a foul septic condition, removal of the submaxillary lymphatic glands should be deferred until a later period, for the reasons mentioned on p. 302, when discussing removal of the entire tongue.

Special instruments.—Mouth gag, long-handled artery and pressure forceps, long scissors with blades curved on the flat, sharp-pointed needle on a handle, and tongue forceps.

Position.—The patient is placed in the dorsal position with a pillow underneath the neck. The operator stands on the affected side and his assistant opposite to him.

Operation.—The gag is inserted between the jaws, the blades separated, and the tongue drawn forwards. Two stout silk ligatures are then introduced, one into each half of the tongue, 1 in. or thereabouts behind the tip, and each tied in the form of a loop about 6 in. long. One of these is given to the assistant, and the tongue being drawn forward, is manipulated by their means throughout the operation.

An incision is made with a scalpel through the mucous membrane on the lower and upper surfaces of the tongue in the middle line; and, whilst traction is exerted laterally by means of the silk ligatures, the median septum is defined at the tip by a few snips with the scissors. When the median septum has been defined, the two halves of the tongue are torn forcibly apart by the surgeon pulling on the ligatures, and separated as far back as is requisite.

Both halves are then held over towards the unaffected side, and the diseased half cut through transversely at its base from without inwards with the scissors. The lingual artery which lies near the lower aspect must be picked up with pressure forceps when it becomes visible, if it has not already been tied by an operation in the neck. Any other bleeding points are also picked up, and ligatures applied to them. The affected half of the tongue is thus removed.

When all hæmorrhage has been arrested, the stump of the tongue is allowed to fall back into the mouth, and the silk

ligature which has been passed through the unaffected half may be fixed to the cheek with a piece of strapping, if it is considered advisable. This ligature enables the tongue to be readily drawn forwards, if hæmorrhage occur owing to slipping of the ligatures.

After-treatment.—The area of operation should be regularly washed out at short intervals with an antiseptic lotion, and care should be taken, especially when the patient is asleep, to guard against the possibility of secretions from the floor of the mouth being drawn into the bronchi and lungs, which may be the starting-point in the development of "*inhalation pneumonia*." This can best be avoided by seeing that the patient lies on the affected side with the head turned outwards, and frequent sponging or washing out the mouth.

Operations for removal of one-half of the tongue, either after splitting the cheek and resection of a portion of the lower jaw, or through an incision in the submaxillary region in the neck, are similar to those which are described in connection with removal of the entire organ, with the exception that the tongue is split in the line of the median septum, and the affected half only removed.

Removal of a "wedge-shaped" portion of the tongue.—This operation is necessary in many cases of macroglossia which are not amenable to other means of treatment, and localised innocent new growths, such as papillomata, lymphangiomata, and nævi. It is also indicated in certain early cases of carcinoma of the tongue in which the disease is limited to the region of the tip or lateral margin.

Operation.—The protuberant portion of the tongue is drawn forwards as far as possible, and a wedge or V-shaped incision made in its substance, the base of the wedge including the protuberant portion. The incision is deepened, the muscular tissues being cut through, until the portion of tongue is removed.

All bleeding vessels are picked up with pressure forceps and ligatured. The incised surfaces are brought into apposition and fixed by the insertion of a number of interrupted sutures. It is advisable to fix the deeper parts together with a few buried sutures. When the wedge-shaped incision is being made, care must be taken not to leave the lateral portion too thin, otherwise the tongue, when recovery has taken place, will be too pointed.

CHAPTER XVI.

OPERATIONS UPON THE CRANIUM.

TREPHINING—

- For fracture of the skull.
- For extra-dural abscess or hæmorrhage.
- For cerebral tumour or cyst.
- For cerebral abscess.
- For cerebellar tumour or cyst.
- For cerebellar abscess.
- Tapping and drainage of the lateral ventricle.
- For the removal of foreign bodies within the skull.
- For epilepsy.

TEMPORARY RESECTION OF THE SKULL.

CRANIECTOMY, OR LINEAR CRANIOTOMY.

Trephining.—In order to expose any of the cranial contents, for the purpose of performing upon them a surgical operation, it is necessary to remove a part of the bony brain case. This is usually done by the aid of an instrument called a trephine. In some cases, however, a chisel and a mallet will be more useful; and in others, especially in those cases in which it is wished to remove a large piece of the cranial vault, a small circular saw, driven by an electric or other form of motor, will be the most efficient.

The operation of trephining will be considered generally, since the methods of procedure in the different operations upon the cranium which involve the removal of bone are somewhat similar.

It will be convenient to first of all consider—(1) The important depressions and prominences which can be felt and seen on the surface of the cranium; and (2) the points which may be determined by means of these; and then (3) the underlying cranial contents which these points serve to indicate.

The glabellar fossa.—This is a depression situated about a quarter of an inch above the root of the nose at the junction of the frontal and nasal bones.

The external occipital protuberance, or inion.—This is a prominence (varying a great deal in size) situate in the middle line at the junction of the vault of the skull and the base posteriorly; from it laterally in each direction extends the *superior curved line* of the occipital bone, forwards to the base of the mastoid process.

The mastoid process.—This conical-shaped prominence is situated immediately behind the ear with the base upwards, and

FIG. 212.—Trephining. Conical trephine with central pin fixed on a circular piece of metal, which fits in the interior of the trephine, and is easily removed.

apex downwards and forwards, whilst the whole extent of its posterior border is easily definable.

The external auditory meatus.—This lies immediately in front of the upper portion of the base of the mastoid, and its cartilaginous continuation forms a sufficiently accurate guide to its bony margins.

The supra-meatal triangle.—This is a small more or less sharply defined depression, immediately above and behind the auditory meatus.

The *zygoma* is the bridge of bone stretching from the anterior margin of the auditory meatus forwards, horizontally to

The *malar prominence*, which is situate at the outer and lower angle of the orbit.

The *external angular prominence* of the frontal bone lies above the malar prominence, and constitutes the upper and outer angle of the orbit.

The *bregma*.—This spot is situate about the bisection of

FIG. 213.—Trephining. Skull showing positions of important bony points, etc.

- | | |
|---|--|
| a. Glabellar fossa. | f. External angular process of frontal bone. |
| b. Bregma. | g. Stephanion. |
| c. Position of parietal foramina. | h. Pterion. |
| d. Lambda. | i. Mastoid process. |
| e. Inion, or external occipital protuberance. | k. Asterion. |

a line drawn vertically between the two external auditory meatuses on the vertex of the skull; whilst, if a point be taken about half an inch posterior to the bisection of the distance between the glabella and external occipital protuberance, a spot will be found that may be termed the *Rolandic spot*, and which also corresponds with the upper point of trisection in a line drawn between the bregma and external occipital protuberance; the lower point of trisection in this line being one to which reference will be made later.

The *pterion* is a spot in the temporal fossa that coincides

with the point of bisection in a line drawn horizontally backwards from the external angular process of the frontal bone, and parallel with the zygoma to a point vertically above the corresponding external auditory meatus.

It may also be found by drawing a line vertically upwards from the centre of the zygoma, the pterion being situated at the point where this line meets the above-mentioned horizontal line; or, if a square be completed on a line drawn between the external angular prominence of the frontal bone and the malar prominence, with the upper border of the zygoma as a second side, the pterion will correspond with its postero-superior angle.

FIG. 214.—Skull, showing position of important cerebral fissures.

- | | | |
|------------------------|--|--------------------------|
| a. Fissure of Rolando. | | c. Pre-central fissure. |
| b. Fissure of Sylvius. | | d. Post-central fissure. |

The *coronal suture* lies between the bregma and pterion; where this suture crosses the temporal crest is the spot known as the *stephanion*, a point the same distance above the pterion as the pterion is above the zygoma, and in the same vertical line.

The *sagittal suture* lies in the middle line for the upper two-thirds of the distance between the bregma and inion; its lower extremity corresponding with the lambda, which can often be felt as a prominence opposite the lower point of trisection in this line.

The limits of the *cerebrum* may be marked out by drawing

a line from a quarter of an inch above the external occipital protuberance behind, to the base of the mastoid process; thence to the upper border of the external auditory meatus; next to the external angular process of the frontal bone in a curved direction, the convexity being towards the prominence of the malar bone; and finally inwards to the middle line, a quarter of an inch above the depression at the root of the nose.

The upper limits of the *cerebellum* can be defined by drawing a line a quarter of an inch below the superior curved line on the occipital bone, and parallel to it, forwards to the centre of the base of the mastoid process; the lower limit is situate about

FIG. 215.—Diagram (after EBERSTALLER) of the fissures and convolutions of the convexity of the right hemisphere of the brain. The relative depth of the fissures is indicated by the shading. The extent of the functional areas is indicated by the dotted lines.

1 in. below the line, but, on account of the soft parts of the neck, can be less accurately marked out.

The division between these two main portions of the brain also corresponds with the attachment of the tentorium cerebelli. The divisions between the *cerebral lobes* are easily defined; the median line between the glabella and external occipital protuberance indicating the division between the cerebral hemispheres and two halves of the cerebellum, and the situation of the falx cerebri and falx cerebelli.

The division between the frontal and parietal lobes corresponds with the *Rolandic fissure*, which may be marked out by drawing a line from the Rolandic spot forwards and downwards at an

angle of $67^{\circ}5$ with the posterior portion of the median line from glabella to inion, which line also corresponds with that joining the Rolandic spot and pterion.

The line of junction of the parietal and occipital lobes is indicated by joining the lower point of trisection in the distance between the bregma and inion with the external auditory meatus; the upper part of this line corresponding to the external parieto-occipital fissure. The separation between the temporo-sphenoidal and parietal lobes corresponds to the line drawn horizontally backwards from the external angular process.

The pre- and post-central fissures lie respectively half an inch

FIG. 216.—Diagram of the fissures and convolutions of the convexity of the left cerebral hemisphere. The speech area is shown in this hemisphere. The motor area is more extensive than on the right side.—ALLEN STARR.

in front and behind the Rolandic fissure, and thus the whole Rolandic area may be indicated.

The main Sylvian fissure reaches the surface of the brain opposite the pterion in three limbs from this point, extending vertically upwards half an inch; directly forwards 1 in.; whilst its posterior continuation runs directly backwards in the horizontal line in which the pterion lies, till vertically opposite the external auditory meatus, where, curving slightly upwards for about 1 in., it terminates.

The *superior longitudinal sinus* lies usually immediately to the right of the median glabella-inion line (for its entire extent), and the *inferior longitudinal sinus* lies opposite the

anterior two-thirds, and the *straight sinus* opposite the posterior third of the line.

The *lateral sinus* lies opposite the superior curved line of the occipital bone, not extending further forwards than the centre of the base of the mastoid process, where it then curves downwards and forwards to a point immediately below the external auditory meatus.

The *anterior branch of the middle meningeal artery* is best sought at the pterion, and its *posterior branch* at a spot vertically above the mastoid process in a line drawn backwards horizontally through this point; whilst the main trunk is opposite a point a finger's-breadth above the centre of the zygoma. The supra-meatal triangle indicates the situation of the *mastoid antrum*.

Special instruments.—Periosteal elevator (straight and bent), bone forceps, gouge forceps, small saw (Hey's), trephine, trephine brush, quill chisel and mallet (circular saw driven by

FIG. 217.—Trephining. Periosteal elevator.—HORSLEY.

a motor, if it is necessary to remove a large piece of bone), fine-toothed forceps, sponge-holders, trocar and cannula.

Position.—The patient is placed in the dorsal position for nearly all operations upon the cranium, with the head turned towards the sound side. The operation table should be of moderate height, so as to allow ready access to all parts of the wound.

Operation.—The operation of trephining may be divided into the following stages, namely—(a) Demarcation, on the external surface of the cranium, of the part of the cranial contents which it is proposed to lay bare; (b) formation of a flap consisting of the soft structures of the scalp; (c) removal of a portion of the cranial bony vault; (d) incision of the membranes of the brain, and exposure of the brain surface, in those cases, such as cerebral tumour or abscess, in which it is necessary to go beyond the membranes; (e) special treatment of diseased part, such as evacuation of pus from a cerebral abscess, or excision of a cranial tumour; (f) closure, complete

or partial, of incision in membranes, and further treatment of wound; (g) after-treatment.

In the operation of trephining, the lines of the meningeal sinuses should be avoided as far as possible, as well as the region of the bony sutures. It is not always possible, however, to avoid the sutures.

(a) *Demarcation, on the external surface of the cranium, of the part of the cranial contents which it is proposed to lay bare.*

—This can be effected by paying attention to the points which have been discussed under anatomical considerations.

(b) *Formation of scalp flap.*—The part to be operated upon having been determined, a semicircular incision is made in the scalp, which comprises this area, and is so situated that the base of the flap is towards the base line of the brain, and the convexity towards the vertex of the skull. The soft structures of the scalp, including the pericranium, should be divided with the scalpel right down to the bone. The periosteal elevator is taken, and the periosteum is detached from the bone, and the flap of soft structures turned down. This flap is held out of the way by a retractor or a silk suture passed through its highest point. All bleeding from the vessels of the scalp is arrested by ligature or pressure forceps.

(c) *Removal of a portion of the bony cranium.*—(1) *By the use of a trephine.*—A trephine is taken, of the shape shown in Fig. 212, the centre pin is introduced, and placed on the centre of the piece of bone which it is wished to remove. The pin is thrust into the bone by a pushing and rotatory movement,

and then by a series of to-and-from circular movements with the hand the teeth of the instrument are made to cut a circular groove in the bone. When a definite groove has been made, the trephine is taken out of the wound, the central pin is removed, and the instrument is again introduced, and the circle of bone gradually sawn through. Care must be taken to avoid using the saw in a jerky manner, otherwise much longer time will be taken in removing the circle of bone. From time to time, as the sawing proceeds, the trephine should be taken from the wound, and the

FIG. 218.—Trephining. Chisel with straight edge.

bone dust brushed out of the groove in the bone and from the teeth of the instrument. When the bone has been nearly cut through, the crown can be lifted out either by a side-to-side movement with the trephine, or by lifting it up with a periosteal elevator. If the removal of one crown of bone does not give sufficient space, a second or even a third may be removed, and the intervening portions of bone detached with a saw or bone forceps.

(2) *With a chisel and mallet.*—In some forms of injury to the cranial vault, the removal of the portion of bone can be effected most readily by the use of a chisel and mallet. This is especially the case in operations for the relief of a depressed fracture, in opening the frontal sinuses, and also in operations upon the mastoid cells. Figs. 218, 219, and 220 are illustrations of instruments which are most useful for this purpose.

(3) *With a circular saw driven by a motor (surgical engine).*—When it is wished to remove a large piece of the bony cranium, as in the removal of a large intracranial tumour, this form of instrument will be found to be the most efficient. No one, however, should attempt to use this instrument in a surgical operation until he has had considerable experience in its use, and knows thoroughly how to manage and control it.

As the portions of bone are removed they are placed in a warm sterilised normal saline solution (0·75 per cent. of common salt).

If the object of the operation is evacuation of an extra-dural collection of pus, ligation of a meningeal artery, or removal of a growth of the bone or a depressed piece of the cranial vault, it will not be necessary to proceed more deeply. These objects can be accomplished through the opening which has already been made.

If the nature of the affection necessitates incision of the membranes, this is now done.

FIG. 219.—Trephining.
Chisel grooved.

(d) *Incision of the membranes of brain, etc.*—Care must be taken, in making an incision through the dura mater, not to wound one of the large venous sinuses. The position of these has already been given. The dura mater is best opened by making a semilunar incision in it, the convexity being towards the vertex. The margins of this incision should be a short distance internal to those of the incision in the bone, so as to allow of closure later. When the flap of dura mater so marked out has been turned down, any cyst or abscess in the subdural space may be dealt with. If it is necessary to proceed further, the arachnoid membrane is incised. This is normally a very thin membrane, and lies in close contact with the pia mater. It may, however, be thickened in diseased conditions. The pia mater, a very vascular membrane, is now laid bare and can be incised if requisite, so as to expose the cortex of the brain in the bottom of the wound.

FIG. 220.—Trephining. Mallet.

(e) *Removal of diseased brain tissue, etc.*—In cases of cerebral abscess, cerebral tumour, or foreign body in the brain, or tapping of the lateral ventricle, the cerebral operation proper can now be carried out. Details of these procedures are given under the headings of the separate operations.

(f) *Further treatment of wound.*—In a non-septic case, when the diseased portion or the foreign body has been removed, all bleeding from the surface of the brain is arrested, and the margins of the incision in the membranes are united by the insertion of fine silk sutures. Next, the portions of bone which have been removed are replaced in their original position, and finally the scalp flap is accurately stitched over them and dry aseptic dressings applied. In septic cases, drainage must be established. The portions of bone removed are not replaced in cases of this kind. Part of the external wound is left open for the exit of the drainage tube, whilst the remainder is closed in the ordinary manner.

(g) *After-treatment.*—The patient must be kept very quiet after the performance of an operation on the brain. In non-septic cases the dressings are left on for a week, and then taken off and the stitches removed. In suppurating cases the dressings must be frequently changed, so as to avoid as far as possible the accumulation of pus or septic fluid within the wound.

For fracture of the skull.—*Indications.*—(a) *Punctured fractures of the skull.*—All cases of punctured fracture should be trephined, and an examination made of the extent of the injury, since in this form of fracture the inner table of the skull is very often driven inwards and splintered, whilst the external wound is small and insignificant.

(b) *Compound depressed fractures.*—It is the safest plan to operate on all cases of this kind, owing to the fact that often particles of dirt which have been carried in at the time of the injury are liable to escape notice and become the cause of supuration. This is especially the case in bullet wounds.

(c) *Foreign bodies* embedded in the bones of the cranial vault, and possibly extending into the brain substance or penetrating the membranes.

(d) *Simple depressed fractures of the skull.*—In adults it is the best and safest plan of treatment to elevate all depressed fractures; the strictest aseptic precautions being observed. If this is not done, in a certain percentage of cases, although there are no symptoms dependent upon the depressed bone at the time of the injury, they are liable to develop later in the form of focal (or Jacksonian) epilepsy.

In children the bones of the skull are more elastic, and tend readily to resume their original position after a depression; hence many such cases may safely be treated on the expectant plan without operation, if there are no symptoms due to the depressed bone or to cerebral hæmorrhage or abscess.

Position.—The patient is placed in the dorsal position, the head turned to the sound side, and supported by one or two sandbags. The surgeon stands on the affected side of the head and his assistant opposite to him.

Operation.—If the patient is unconscious as the result of the injury, an anæsthetic is not necessary. If, however, one is required, chloroform is the best.

An incision, semilunar in shape if possible, is made, which divides everything down to the bone. A flap is turned downwards with the periosteal elevator, or, if muscle has to be detached, as when the injury involves the temporal fossa, with the scalpel. The flap should be large enough to fully expose

the fracture and the adjacent portion of sound bone, the convexity of the flap being towards the vertex of the skull.

The extent and nature of the fracture is now ascertained. If there has been much splintering of bone, it is often possible to elevate or remove the depressed pieces with dressing forceps. If this cannot be done, a crown of bone must be removed with the trephine, which will allow the elevation of the depressed fragments. A point is selected on one margin of the depressed portion, and the trephine, with the pin protruding, is placed upon it in such a manner that the pin rests upon sound bone. If it is thought that there has been much splintering, and that a

FIG. 221.—Trephining. Depressed fracture of the skull in frontal region, showing place where a trephine should be applied.

sharp fragment has been driven into the brain, the entire circle of the trephine must rest upon sound bone. The area to be trephined having been determined, a crown of bone is removed in the usual manner. The elevator can now be inserted underneath the depressed portion, and elevation accomplished. The margin of the trephine aperture on the sound bone is used as a fulcrum in lifting up the depressed part.

If hæmorrhage is taking place from the bottom of the wound, after the circle of bone has been removed, it may come from a branch of one of the meningeal arteries, usually the middle, from one of the sinuses, or, if the dura mater has been punctured, from the surface of the brain. In each case the site of bleeding

must be ascertained, and a ligature applied to the bleeding point, or the wound packed with a strip of gauze.

When all hæmorrhage has been arrested, any tear in the dura mater is closed by the introduction of sutures. Next, the fragments of bone are replaced as far as possible in their original position, if they are not contaminated with dirt, care being taken not to allow any sharp edge to project towards the meninges. The margins of the incision in the scalp are brought together and fixed in apposition by sutures. One angle of the wound is left open, and a drain of gauze passed down to the region of the fractured bone. Antiseptic dressings are lightly applied, and fixed in position by strapping and a bandage.

After-treatment.—In favourable cases the fragments will unite, and the external wound will heal by first intention. Should suppuration occur, free drainage must be maintained, and fomentations applied.

If a large gap is left in the cranial wall, owing to non-union of the fragments, it may be necessary to provide the patient with a metal plate, which shall accurately cover the aperture in the bony skull, and help to protect it from injury. This is carried out at a subsequent date. The metal plate is usually placed external to the skin, but in some cases it has been placed directly upon the bone. The former is the better plan.

For extra-dural abscess or hæmorrhage.—*Abscess.*—The formation of an extra-dural abscess is usually preceded by an injury to the cranial bones overlying the seat of the abscess, the injured bone having become the seat of suppuration which has extended through it to the dura mater, owing to the development of a septic osteitis or osteomyelitis. An extra-dural abscess may also develop as the result of general pyæmia, but more commonly it is a precursor of this condition.

When an extra-dural abscess has formed, it usually causes the appearance of symptoms of hemiplegia, but often this condition is not well marked, or is masked by symptoms dependent upon general pyæmia. In every case, however, in which the presence of pus between the bone and dura mater is suspected, or in which the bone is the seat of a septic, infective, or suppurative process, trephining ought at once to be performed, and the diseased bone and the collection of pus removed. Stringent antiseptic treatment is then carried out, with the object of preventing further extension of the suppurative process and the elimination of the diseased tissues.

The actual operation in this case is similar to that described

above. Free drainage must be established, and frequent irrigation ordered.

Hæmorrhage.—The operative treatment of this condition is fully considered on p. 383, in connection with ligature of the middle meningeal artery.

For cerebral tumour or cyst.—The operations for the removal of tumours or cysts of the cerebrum are essentially similar, and

FIG. 222.—The head of an adult female, in which the brain is exposed *in situ*. Bars of bone are left along the lines of the cranial sutures, and also along the line of the temporal ridge.
—CUNNINGHAM.

will be considered together. An investigation of the nature of tumours which affect the brain has shown, from an analysis of a hundred cases, that forty-five were tuberculous, twenty-four gliomata, two glio-sarcomata, ten sarcomata, five carcinomata, one lymphoma, one myxoma, four cysts, five gummata, and three doubtful.

Indications.—(a) The presence of a tumour of the cerebrum, which is primary in nature, and is not associated with secondary growths elsewhere. In the case of tuberculous tumours, the

absence of general tuberculosis must be established before an operation is undertaken. In the case of a gumma, prolonged treatment with potassium iodide must be tried before an operation is performed.

(b) The presence of a cyst of the cerebrum, or of the arachnoid, which is pressing upon the brain and causing symptoms.

(c) The presence of a tumour of the dura mater, or of a cranial bone which has extended inwards and is causing symptoms of irritation, etc., owing to pressure upon the brain matter.

Localisation of tumour or cyst.—Before commencing an

FIG. 223.—Trephining. Skull, showing positions where trephine ought to be first applied in exposing motor centres.

a. Leg. | b. Arm.
c. Face and head.

operation upon the cerebrum for the removal of a tumour or cyst, its position within the cranial cavity, or at least the portion of brain which is being pressed upon, is determined from a consideration of the symptoms which have a localising significance.

Operation.—A large semicircular flap of the scalp is turned down in the usual manner, so as to expose the bone overlying the affected portion of the brain. With the trephine, two or more crowns of bone are removed, the intervening bridge of osseous tissue cut through with the chisel, and the dura mater fully exposed. If the growth has sprung from the internal aspect of one of the cranial bones, it will be discovered at this

stage, and can be removed. When the underlying portion of the dura mater or the brain has been involved in a growth from the internal surface of a cranial bone, the infiltrated portions are removed, provided that they are not too extensive. If the bone or the exposed part of the dura mater is not the seat of origin of the tumour, the dura mater is divided in the usual manner, so as to expose the surface of the brain covered by the arachnoid and pia mater. If the growth has arisen from the deep aspect of the dura mater, it is now visible and can be extirpated; or if there is a cyst in the arachnoid, or in the superficial portion of the exposed part of the brain, it can be dissected out and removed.

When a tumour of the cerebrum is being dealt with, the arachnoid and the pia mater are incised, and the limits of the tumour defined. In some cases the cortex of the brain will require to be incised before the tumour becomes visible. Usually, however, its location will be manifest before making an incision of this kind. When the locality and extent of the tumour have been determined, the brain substance is incised with a sharp scalpel all round the tumour, at right angles to the surface. By this means the tumour is freed except on its deep aspect; it is lifted up, and its deep connections with the brain cut through. It can now be removed. Hæmorrhage may take place at this stage, but it can usually be readily arrested by packing the wound with strips of dry aseptic gauze and applying slight pressure.

In many cases it will be found advisable to defer the removal of the cyst until several days after it has been exposed. When the membranes have been incised, an aseptic dressing is applied, and the patient sent back to bed. After three or four days the membranes will have become adherent to the margins of the incision, and then removal of the tumour is effected as above.

After the removal of the tumour or cyst, and the arrest of all hæmorrhage, the margins of the incisions in the dura mater are united by sutures, and the external wound closed.

Sarcomatous growths which arise in or involve the cerebrum, are very prone to recurrence, but even in these cases some improvement of the patient's condition may be effected, and life be prolonged by the operation.

In the case of non-malignant tumours or of cysts the prognosis is much more hopeful.

For cerebral abscess.—An abscess may involve any portion of the cerebrum, and its locality depends upon the pathological condition which has caused it. Thus, in abscess of the brain

dependent upon middle ear disease, it is usually located either in the posterior portion of the temporo-sphenoidal lobe, or in the anterior and external portion of the lateral lobe of the cerebellum of the corresponding side. When the abscess is due to an injury such as a perforating wound, it is situated in the injured area, whilst if it is due to pyæmia it may be located in any portion of the brain. In the latter case, multiple abscesses are often met with.

Indications.—(a) *Abscess of the cerebrum, dependent upon a suppurative affection of the middle ear.*—This is usually located in the lower and posterior part of the temporo-sphenoidal lobe of the affected side.

(b) *Abscess of the brain due to an injury.*—If the injury is a perforating one, or the abscess has formed around a foreign body within the brain, the nature of the injury and its point of application will help to determine the locality of the pus. When the abscess is developed in connection with a foreign body, such as a bullet, X-ray photography may help to define the position. In these cases a photograph must be taken in both the antero-posterior and the transverse direction.

(c) *Pyæmic abscess of the cerebrum.*—If there is reason to think that a pyæmic abscess of the brain is single, and there are not pyæmic abscesses elsewhere, it is advisable to operate. If, however, an abscess of the brain is only one of a number of pyæmic abscesses, it is scarcely advisable to perform an operation, as good results can scarcely be expected to follow. Each case of pyæmic abscess of the brain must, however, be considered on its merits, and no general rules can be given as to operation.

Operation.—*For an abscess of the temporo-sphenoidal lobe.*

An abscess of the temporo-sphenoidal lobe, when it is due to extension of a suppurative process from the middle ear, is usually situated, in an adult, underneath a point 1 or $1\frac{1}{4}$ in. above and slightly behind the external auditory meatus.

An incision is made through the scalp in a line corresponding to the free margin of the auricle, and a flap including all the soft structures turned forwards. In the anterior and upper part of the flap a portion of the temporal muscle will be included. The trephine is then applied in such a manner that the pin is upon a point 1 in. above the external auditory meatus, as shown in Fig. 224. A trephine with a diameter of 1 in. should be used. The crown of bone having been removed, the dura mater is incised, care being taken to avoid the posterior branch of the middle meningeal artery, or, if it is in the way, it should

be ligatured before division. The surface of the brain will now be exposed, and often the subdural and subarachnoid spaces will be obliterated in the exposed area by inflammatory adhesions. In cases of suppuration, the cerebral substance will protrude into the wound, and the position of the abscess can be seen. If it is not visible from the surface, a trocar and cannula should be carefully pushed inwards so as to find the exact situation of the pus. When this has been done, a grooved director is passed into the abscess cavity along the side of the trocar, an incision is made through the overlying brain substance, and the pus evacuated, care being taken to protect the margins of the in-

FIG. 224.—Cerebral abscess. *a*. Point for applying trephine in abscess of temporo-sphenoidal lobes.

cision with strips of aseptic gauze. The cavity is irrigated with an antiseptic solution and a drainage tube passed into the bottom of the cavity and stitched to the inferior angle of the external incision. The remainder of the incision is closed by the insertion of sutures. When there are no adhesions between the dura mater and the affected portion of the brain, it is probably safer, after the pus has been evacuated, to carefully pack the interior of the abscess cavity, for the first few days, with strips of antiseptic gauze, so as to avoid, if possible, the spread of the inflammation to the meninges at the base. If the tube is used in these cases from the first, the pus is liable to escape along its side and gravitate towards the base of the brain.

It is not advisable to replace the bone in cases of this kind.

When the locality of the pus is not exposed by the removal of the first trephine crown, a second one should be taken out, or the original opening enlarged with a chisel or with gouge forceps.

For cerebellar tumour or cyst.—The diagnosis of tumour or cyst of the cerebellum is difficult, owing to the uncertainty of the symptoms which are produced by growths in this situation. When, however, it is possible to make a diagnosis, with a reasonable amount of certainty, that a tumour or cyst of the cerebellum is present and is confined to one side, an attempt should be made to remove it by operation.

Position.—The patient is placed in the semiprone position, and lying upon the sound side. The neck is supported by a sandbag. The operator stands behind the patient, and his assistant opposite.

Operation.—An incision, semicircular in shape, is made, commencing at the posterior aspect of the apex of the mastoid process, and extending upwards to the base of the mastoid, and then along the superior curved line of the occipital for two-thirds of the distance towards the external occipital protuberance. This

incision is extended down to the bone. In the first part the cut fibres of the sterno-mastoid will be divided, and internally the occipital artery must either be pulled aside or ligatured and divided. It will be found crossing the superior curved line of the occipital bone at the inner part of the incision. With the scalpel and periosteal elevator a flap is turned downwards so as to expose the posterior aspect of the base of the mastoid, and that portion of the occipital bone which lies below the superior curved line. Care must be taken not to separate the soft structures too far inwards, otherwise the spinal canal may be opened, and the medulla injured between the occipital bone and the atlas. When a sufficient area of bone has been exposed, a trephine is applied and a circle of bone removed. In

FIG. 225. — Trephining cerebellum. Line of incision in operation for abscess or tumour of lateral lobe of cerebellum.

doing this, care must be taken to place the trephine below the line of the lateral sinus. The bone in this region is often very thin, in which case it can be readily removed with a chisel and mallet. When the bone has been removed, the dura mater is opened by making a semilunar incision in it with the base towards the lateral sinus. The cerebellum is now exposed, and the tumour or cyst sought for, after the manner mentioned in connection with tumours of the cerebrum.

The further treatment is similar to that recommended in connection with cerebral tumours and cysts.

For cerebellar abscess.—Cerebellar abscess occurs in the majority of cases as a complication of mastoid disease. It may occur, however, in the course of pyæmia, or as a result of an injury. Whenever its existence can be diagnosed an operation is indicated, unless general pyæmia is present and there is no hope of good results following operative interference.

Operation.—An abscess of the cerebellum usually involves the anterior and external portion of one lateral lobe.

An incision is made similar to that described in the preceding paragraph, and the abscess exposed. Evacuation and drainage is established as in an abscess of the temporo-sphenoidal lobe of the cerebrum (*q.v.*, p. 328).

Tapping and drainage of the lateral ventricle.—This operation has been performed for hydrocephalus, but as yet with very poor results.

Operation.—The side of the skull upon which it is proposed to operate having been decided, an aperture is made in the skull $1\frac{1}{4}$ in. above and slightly behind the external auditory meatus, as in trephining for temporo-sphenoidal abscess (Fig. 224). When the dura mater has been turned aside, a trocar is pushed inwards towards a point $2\frac{1}{2}$ in. above the external auditory meatus of the opposite side. After pushing the trocar or needle through a variable thickness of brain matter, diminished resistance is experienced to the passage of the trocar, and fluid escapes. The fluid is allowed to escape slowly. If it is wished to drain the ventricle, a tube is passed inwards, and fixed in position by stitching it to the margins of the parietal wound.

For the removal of foreign bodies within the skull.—In the treatment of compound depressed or punctured fractures of the skull, it is often necessary to seek for and remove foreign bodies.

In these cases the trephine is applied in the region of the fracture, and an attempt made to trace the course of the bullet or other foreign body from its aperture of entrance.

It occasionally happens, however, that a bullet becomes embedded either in the brain or the membranes, and gives rise to no localising symptoms. In these cases, if it is thought necessary to attempt the extraction of the bullet or foreign body, an X-ray photograph should be taken in order to find out where the foreign body has become fixed.

In the first class of cases a light bullet-probe is passed along the wound, the instrument being allowed to find its way more by its own weight than by pressure exerted by the surgeon. If a hard substance is felt, bullet forceps are passed along the probe, and an attempt made to extract the foreign body.

When the missile has passed through the brain, and is located on the opposite side of the skull to the fracture, it is advisable to make a second trephine opening over the foreign body, and remove it through this. Such a method of treatment, especially in the case of irregular and angular bodies, entails less injury to the brain substance, than when it is removed with long forceps through the aperture of entrance.

When the position of a bullet or foreign body has been located within the cranium by the aid of two X-ray photographs, one taken in an antero-posterior and the other in a transverse direction, it is marked out on the surface of the scalp with an aniline pencil. Next, a semilunar flap of the scalp is turned down in the usual manner, and the bone removed with a trephine. The dura mater is incised if necessary, and the brain substance as well, when the bullet is underneath the cortex, and by this means the foreign body is laid bare. It is seized by forceps of appropriate shape, and removed. All hæmorrhage from the brain tissue is arrested, the incision in the dura mater is sewn up, the fragments of bone are replaced in their original position, and the scalp wound closed by a series of interrupted sutures.

When the bullet or foreign body has given rise to suppuration, the cavity is treated according to the method described in connection with cerebral abscess.

Operative treatment of epilepsy.—*Indications.*—Whenever the fits of epilepsy repeatedly commence by movements in a small and definite group of muscles, it is justifiable to expose that portion of the cortex of the brain in which the cortical centres for these muscles are located. If a tumour of the bone or meninges, or a cyst or tumour of the cerebrum is found, it is removed, according to one of the methods previously described.

If, however, the exposed part of the cortex of the brain is

apparently healthy, and no tumour can be discovered in the subcortical tissue, it does not appear to be justifiable to remove a wedge-shaped portion of brain tissue which shall include the cortical motor centres of the affected group of muscles. If this is done, the corresponding muscles become paralysed and the limb useless. Moreover, the scar which results from the removal of a portion of the brain will usually contract and affect the adjacent motor centres.

Temporary resection of the skull.—The term “temporary resection of the skull,” or osteoplastic resection, is given to that operation in which a flap of the skull wall is turned back without

detaching it; and, after an examination has been made of the exposed cranial contents, or an operation has been performed upon them, this flap is replaced in its original position, fixed by the insertion of a few sutures, and then covered by closure of the external wound in the scalp.

Indications.—This operation appears to be indicated in cases in which it is advisable to make an examination of the cranial contents, or in which a large piece of bone must be removed in order to obtain the requisite amount of room for the removal of an intracranial tumour.

Operation.—An incision, Ω shaped, is made down to the bone with a scalpel. With a surgical

FIG. 226.—Temporary resection of skull. Method of turning down a flap.—After WAGNER.

engine, or a saw, the bony wall of the cranium is divided for the entire length of the incision. Next, the portion of bone which has been partially detached is forcibly lifted up and turned downwards together with the overlying part of the scalp. In old people, or people with thick cranial bones, it will usually be necessary to partially divide with a chisel the piece of bone in the base of the flap. With a curved or bent periosteal elevator, the dura mater is detached from the internal surface of the bones of the skull as the flap is turned down.

The examination of the intracranial contents is now made, the dura mater being divided in the line of the original incision, if necessary.

When the intracranial examination, or further operation, has been performed, the margins of the incision in the dura mater are approximated and united with sutures, and the flap of bone and soft tissue of the scalp is turned back into its original position, and fixed by the insertion of sutures.

If sufficient tissue is not left at the attached part of the bone flap, the reflected piece of bone is liable to necrose, especially in people who are no longer young.

Craniectomy, or linear craniotomy.

—The operation of craniectomy has for its object the removal of a portion of the bony cranium.

Indications.—(a) Some forms of microcephalus, in which there has been premature union along the lines of the sutures.

(b) Cases of early closure of the sutures, dependent upon synostosis of the cranial bones, and necessarily associated with microcephalus, but usually with epilepsy.

A linear piece of the parietal bone, parallel to the sagittal suture and a short distance external to it, is generally removed. Portions of the frontal and occipital bones may be removed as well.

Operation.—An incision is made parallel with and slightly external to the superior longitudinal sinus, commencing at the lambda and terminating at the bregma or a point more anterior; this divides all the soft tissues of the scalp, including the pericranium. A flap is dissected outwards for a short distance, and then a trephine, half an inch in diameter, is used to remove a crown of bone. Cutting forceps or Keen's forceps are then taken, and a strip of bone half an inch in width is removed for the entire length of the incision, from the exposed portion of the parietal bone, and also from the occipital and frontal bones if it is considered to be requisite. This strip

FIG. 227.—Forceps (Keen's) for removing portions of cranial bones.

of bone may be removed with a Hey's saw. The perieranium is removed along with the bone. Care must be taken not to injure the dura mater, since in cases which require this operation it is usually closely adherent. When the strip of bone has been removed, all bleeding is arrested, and the external wound closed by sutures.

Usually it is only necessary to perform the operation upon

FIG. 228.—Hey's saw.

one side; if, however, the nature of the case necessitates a bilateral operation, a similar portion of bone must be removed from the other side. This is done after the patient has quite recovered from the first operation.

The results which have followed the performance of this operation have as yet not been good. Since, however, the cases are hopeless without operation, it is generally advisable that some surgical measure such as the above should be attempted.

CHAPTER XVII.

OPERATIONS UPON THE SPINAL COLUMN AND SPINAL CORD.

LAMINECTOMY.

OPERATIONS FOR SPINA BIFIDA—

1. By injection.
2. By excision.

OPERATION FOR CARIES OF THE BODIES OF THE VERTEBRÆ.

LUMBAR PUNCTURE.

Laminectomy.—Laminectomy is an operation which has for its object the division of the laminae of one or more vertebræ.

Indications.—(a) Caries of the spinal column accompanied by the formation of inflammatory products which cause pressure upon the spinal cord.

(b) Fractures of the spinal column in which a piece of bone presses upon the spinal cord or causes intraspinal hæmorrhage.

(c) Intraspinal tumours or cysts which are thought to be capable of removal.

(d) Foreign bodies, such as bullets or pieces of broken knives, within the spinal canal.

Special instruments.—Resection knife, periosteal elevator, Hey's saw, wide retractors, bone forceps, fine-toothed forceps and fine scissors, chisel and mallet, laminectomy forceps.

Position.—The patient lies in

FIG. 229.—Laminectomy. a.
Position of incision for lower
dorsal region.

the semiprone position close to one edge of the table. The surgeon stands behind the patient, close to the region of the spine upon which he is going to operate. His assistant stands opposite to him.

FIG. 230.—Laminectomy forceps.

Operation.—The region of the spinal column upon which it is proposed to operate having been decided, a vertical incision 4 in. in length is made in the middle line of the back, the centre of the incision being opposite the centre of the affected portion of the spine. With the resection knife, the erector spinæ muscles are separated from the spines and laminae of the vertebrae, the periosteum being detached along with the muscles as far as possible. By this means the posterior aspect of the vertebrae is exposed. A special form of bone forceps (Fig. 230) is now taken, and the smaller blade passed beneath one of the laminae of the lowest vertebra upon which it is proposed to operate, and the lamina divided close to its junction with the transverse process. The laminae may be partially sawn through with a Hey's saw (Fig. 228) before division. This procedure is repeated upon the opposite side. The ligamenta subflava which fix the lower borders of the partially separated laminae to the vertebra below are divided with the scalpel, and then the united laminae and spinous processes are raised upwards. The laminae of the vertebra above are divided in a similar manner, and lifted up along with the first. By this means a bony and ligamentous flap, consisting of the laminae and

intervening ligaments of two vertebrae, is partially separated and lifted upwards, and the interior of the spinal column opened.

Any tumour or cyst, projecting spicule of bone, sequestrum, or collection of tuberculous material or blood, can now be dealt

with. If more space be required, the laminae of one or more additional vertebrae may be divided.

If it be necessary to expose the spinal cord, the intraspinal veins and fatty tissue are pulled aside and the dorsal aspect of the dura mater exposed. A vertical incision is made through this in the middle line, either with the scalpel or with fine scissors and toothed forceps. The margins of this incision are held apart, and the spinal cord, together with the region of the spinal nerves, laid bare. If hæmorrhage has taken place within the dura mater, the blood is removed.

When it has been found necessary to open the dura mater, the incision is afterwards closed with a series of fine silk sutures.

In those cases in which the operation has been done for fracture of the spinal column, intraspinal hæmorrhage or tumour, the bony and ligamentous flap is replaced and the wound closed by the insertion of sutures.

In inflammatory or tuberculous cases the laminae are usually entirely removed; the upper part of the wound is closed with sutures, and the lower part left open for drainage.

Operation for spina bifida.—*Indications.*—Those cases of spina bifida which do not tend to undergo spontaneous cure, and in which a fatal result is to be apprehended in the absence of surgical treatment.

Operation.—Two methods of treatment have been made use of, one of which consists in the injection of an irritant fluid into the sac, and the other in complete removal of the sac.

(a) *Injection.*—The fluid which is generally used for this purpose consists of a mixture of iodine, iodide of potassium, and glycerin, in the following proportions:—Iodine, 10 grs.; potassium iodide, 30 grs.; glycerin, 1 oz. (Morton's fluid).

Injection should be limited to those cases in which the spinal cord does not occupy the interior of the sac.

A long fine needle, to which is attached a small syringe, is pushed into the base of the tumour, care being taken that it passes through sound tissue. The fluid is withdrawn from the

FIG. 231.—Spina bifida. Operation for radical cure. Line of incision through skin over lateral margins of tumour.

interior of the swelling, and then 1 or 2 drms. of the injection fluid are introduced.

This operation generally has to be repeated several times in order to effect a cure.

(b) *Excision*.—An oval-shaped incision is made around the base of the tumour (Fig. 231), and the sac dissected from the surrounding tissues until the margins of the deficiency in the wall of the spinal canal have been reached. The sac is now opened, the contained fluid allowed to escape, and any nervous structures which may happen to be within the sac returned, if possible, into the spinal canal. The distal portion of the sac is cut away, and the margins of the aperture which is left carefully approximated by the insertion of numerous fine silk sutures. The erector spinæ muscles on each side of the opening are separated for a short distance, and then united over the stump of the sac. The operation is completed by closing the skin incision in the usual manner.

Operation for caries of the bodies of the vertebræ.—An operation may be performed for the removal of collections of pus, which are dependent upon caries of the anterior portions of the bodies of the vertebræ in the lumbar and in the dorsal region.

Special instruments.—Large flat retractors, bone forceps, sequestrum forceps, Volkmann's spoon.

Position.—The patient is placed in the semiprone position, lying upon the sound side, with a pillow beneath the loin. The surgeon stands behind the patient, and the assistant opposite to him.

Operation.—A vertical incision 3 in. in length is made in the lumbar region, over the outer part of the erector spinæ muscle, commencing above a short distance below the lower border of the last rib. The skin, fascia, and sheath of the erector spinæ muscle are cut through and the vertical fibres of the muscle laid bare. This muscle is strongly drawn inwards, in order to expose the middle layer of the lumbar aponeurosis, which forms the anterior portion of its sheath. With the left forefinger the surgeon feels for the apices of the transverse processes of the lumbar vertebræ in the floor and inner part of the wound. When these bony prominences can be felt, a vertical incision is made through the anterior layer of the sheath of the erector spinæ immediately external to these processes. The lamina of lumbar aponeurosis thus divided is drawn outward so as to lay bare the posterior aspect of the quadratus lumborum muscle, the fibres of which run in a slightly oblique direction.

The fibres of this muscle are detached from the transverse processes, care being taken to avoid the lumbar arteries and their branches. These vessels lie in the intervals between the transverse processes. When the quadratus lumborum has been separated, it is retracted outwards. The posterior aspect of the sheath of the psoas muscle is now exposed. The muscle is detached from the transverse process of one of the vertebræ and an aperture made into the abscess cavity. The surgeon's forefinger is then passed along the anterior aspect of one of the transverse processes until the body of the vertebra is reached.

The aperture in the sheath of the psoas muscle can now be increased to any desired extent, and the contents of the abscess cavity removed. The forefinger should examine the interior of the abscess in order to locate the different pouches and pockets, and also the presence of pieces of necrosed bone.

These latter are removed with sequestrum forceps, and then the interior of the abscess cavity is irrigated with an antiseptic solution, such as perchloride of mercury (1 in 2000).

After irrigation, the wall of the abscess cavity is scraped with the surgeon's forefinger, or some form of blunt instrument, in order to detach as much of the lining membrane as possible.

Careful sponging with small sponges on holders will often help materially in removing all flakes of tuberculous material. The cavity is again irrigated, then carefully sponged dry, and the external wound closed by the introduction of sutures. Buried sutures should be used for the closure of the deeper parts of the wound.

After-treatment.—The patient is kept in bed at absolute rest until the parts have healed. Often this entails rest in bed for several months.

Lumbar puncture of the spinal canal.—*Indications.*—The indications for this operation are in cases of hydrocephalus, where it is performed in order to effect drainage, or for the purposes of injection of some anæsthetic solution, and for purpose of diagnosis in bacterial affections of the brain and spinal cord.

Special instruments.—Fine trocar and cannula, and injection apparatus.

Position.—The patient lies in the semiprone position, with the thigh flexed on the abdomen, and the surgeon stands behind him; or he may be seated with the head and shoulders bent forwards, the object in both cases being to separate the lumbar spines and laminae.

Operation.—The space between the fourth and fifth lumbar

vertebra is selected, a point which lies immediately below the bisection of a line drawn transversely below the highest parts of the iliac crest. With the left index finger on the fourth lumbar spine, the trocar is thrust into the vertebral canal about a quarter of an inch to one side and just below this prominence, the point being directed inwards and slightly upwards.

Should the needle engage bone the direction is inaccurate, and it is best to withdraw it a little and thrust it in through the same skin puncture a little lower, since manipulations of the buried needle give pain, and risk breaking it against the laminae.

The point of the needle having found the canal, the trocar is withdrawn, when some drops of cerebro-spinal fluid should run from the cannula, and the required measures may then be adopted. The end of the spinal cord is situate, in the adult, opposite the lower border of the first lumbar vertebra, and in the child opposite the lower border of the second.

The average distance from the surface is a little more than 1 in.

CHAPTER XVIII.

OPERATIONS UPON THE NOSE AND ITS ACCESSORY CAVITIES.

REMOVAL OF NASAL POLYPI—

With a snare.

With forceps.

RECTIFICATION OF DEVIATED NASAL SEPTUM.

PLUGGING THE ANTERIOR AND POSTERIOR NARES.

PASSAGE OF EUSTACHIAN CATHETER.

REMOVAL OF NASO-PHARYNGEAL POLYPUS—

(a) Through the nose.

(b) Through the mouth.

(c) After resection of the upper jaw.

REMOVAL OF ADENOID GROWTHS FROM THE NASO-PHARYNX.

EXPLORATION OF FRONTAL SINUS.

EXPLORATION OF ANTRUM OF HIGHMORE.

Removal of nasal polypi.—Mucous polypi of the nose usually grow from the connective tissue or periosteum covering the turbinated bones, a fact which must be remembered when an attempt is being made to detach them.

Occasionally a nasal polypus may be fibrous in character, in which case it will be found to take its origin either from the roof of the nose, or from the periosteum covering one of the bones which enter into the formation of the nasal cavity. In still rarer instances the polyp may be sarcomata.

Nasal polypi may be removed either with some form of snare or galvanic wire loop, or with forceps. When sarcomatous polypi have to be removed, it is necessary to perform a more radical operation, and the nasal cavity must be opened up, as in Rouge's operation.

(a) **Removal by snare or galvanic wire loop.**—The interior of the nose should be painted with a 10 per cent. solution of hydrochlorate of cocaine before the operation is commenced.

Special instruments.—Wire snare or galvanic wire loop connected with a battery, probe, nasal speculum, lamp, and forehead mirror.

Position.—The patient is seated in a chair of suitable height, with his back towards the source of light, whilst the surgeon sits opposite the patient, and facing the source of light.

Operation.—The nasal speculum (Fig. 232) is introduced into the anterior nasal aperture of the affected side, and the blades separated. The position of the polypus is made out, a probe being used, if requisite, to define its attachment, and then the wire loop of the snare is passed around it (Fig. 233). If the loop of an electric cauterity is used, the current is turned on sufficiently to heat the wire to a dull red heat, and the base of the pedicle cut through. If the electric cauterity is not available, the base of the polypus is cut through by tightening the wire loop. The polypus is next removed from the nose through the speculum. Other polypi are sought for, and dealt with in a similar manner, until all have been removed. The nostril of the other side is next examined, and any polypi which are present removed.

FIG. 232.—Nasal speculum.

Sometimes it is necessary, when the inferior or middle turbinated bones have localised projections or spurs, to remove these, in order to obtain a good view of the upper part of the nose.

It is necessary to keep the nose as free from blood and mucus as possible during the operation, otherwise small polypi will escape removal. These will afterwards increase in size, and necessitate a further operation.

The galvanic wire loop is the most convenient to use for the removal of nasal polypi, since it causes very little hæmorrhage.

(b) Removal with forceps.—The preparation of the patient, the instruments, with the exception that the wire snare or loop is replaced by nasal forceps (Fig. 234), and the positions of the patient and operator, are the same as in the preceding operation.

Operation.—The nasal speculum having been introduced, the position of the polypi is made out. Next, the blades of the nasal forceps are introduced through the aperture in the speculum, the polypi are seized near their bases, and forcibly avulsed. Usually small portions of the turbinated bones, together with the mucous membrane covering them, are pulled away when the forceps are used. When the polypi are located far back in the

region of the naso-pharynx, their removal can be facilitated by passing the forefinger of the left hand behind the soft palate (from the mouth), and pushing the growths between the blades of the forceps, which have been passed backwards along the inferior meatus of the nose.

This method of operation is accompanied by more hæmorrhage than the preceding one.

FIG. 233.—Wire snare for removal of nasal polypi.

FIG. 234.—Nasal polypus forceps.

After-treatment.—Hæmorrhage caused by the removal of non-malignant nasal polypi usually stops spontaneously, shortly after the operation. If it continues, it may be necessary to pack the naso-pharynx, or the nostril, with strips of aseptic gauze. Before this is done, injection of hot water (118° F.) should be tried.

Afterwards the nose is irrigated twice daily with a dilute antiseptic solution, such as Condyl's fluid or boracic acid. This

treatment is continued for a few days, until all discharge from the nose has ceased.

Rectification of deviated nasal septum.—A small amount of deviation of the nasal septum to one or other side is commonly met with, but unless it is considerable no inconvenience is caused

FIG. 235.—Walsham's forceps for rectification of deviated nasal septum.

by it. When, however, the deviation is considerable, and causes practical obliteration of one-half of the nasal passage, it is advisable to attempt to remedy the condition by a surgical operation.

Instruments.—Nasal speculum and forehead mirror, nasal forceps (Walsham), and nasal plugs. If there is a prominent septal spur, a pair of strong scissors will also be necessary.

Operation.—The patient having been anaesthetised, an examination of the nasal septum is made through the speculum, in order to locate the position of the deviation, and any spur which may happen to be present. With the scissors, the spur, if present, is first cut away. Next, the nasal forceps are introduced, one blade on one side of the septum through one nostril, and the other on the other side (Fig. 235). The blades are placed over the most prominent portion of the deviation, and then the handles are approximated. This causes a fracture of the bony part of the deviation. When this has

FIG. 236.—Walsham's vulcanite plugs, for use after septum has been straightened with forceps.

been done successfully, the nasal plugs (Fig. 236) are taken and fixed in the nostrils, one on each side of the septum. Vulcanite plugs are best for this purpose, since they can be softened in hot water, and then moulded to the shape of the nose of the case being dealt with. The plugs are fixed in position by a piece of strong strapping. When plugs are not available, two short pieces of red rubber drainage tube of suitable calibre may be used instead.

After-treatment.—The plugs are taken out daily, the nostrils are irrigated with a dilute antiseptic solution, and then they are replaced. The plugs are worn until the fractured septum has united.

Plugging the anterior and posterior nares.—*Indications.*—Plugging of the posterior nares may be required in the following conditions:—

(a) Severe long-continued bleeding from the nose, which cannot be arrested by simpler measures.

(b) As a preliminary preparation for certain operations on the face and nose, in order to prevent blood from passing into the pharynx.

Special instruments.—Bellocq's sound, strong ligature silk, and gag.

Position.—The patient should be placed in the dorsal position, with the head slightly raised. The surgeon stands on the right side of the patient.

Operation.—A piece of strong ligature silk is passed through the eye of a Bellocq's sound (Fig. 237); the sound is passed along the inferior meatus of the nose of the affected side, until the naso-pharynx is reached, and the spring is then protruded. The mouth is opened, and the gag placed between the teeth, and one end of the ligature is drawn out of the mouth with a pair of forceps. The sound is withdrawn from the nose, one end of the ligature being brought out along with it.

An oblong-shaped pad of gauze, usually about 1 in. long and half an inch thick, sufficiently large to plug the posterior nasal aperture of one side, is made, and two pieces of strong silk fastened to it. The free extremities of one of these are tied to the ligature in the mouth. Traction is now exerted upon the silk thread in the nose, by which means the extremities of the ligature are brought out through the anterior nares. With the left forefinger the plug of gauze is passed behind the soft palate and fitted into the posterior nasal aperture.

A second plug of gauze, half an inch in thickness, is now taken and placed between the two ends which protrude from the anterior nasal aperture. These are drawn tight, and tied over the pad. The second ligature attached to the plug has one end cut short before the plug is introduced, whilst the other is allowed to hang down into the pharynx. It is used for withdrawing the plug.

If hæmorrhage is taking place from both sides of the nose, the other posterior nasal aperture may be plugged in a similar manner.

After-treatment.—These plugs should not be allowed to remain in position for more than twenty-four or thirty-six hours without being changed, and the nasal cavity washed out.

FIG. 237.—Bellocq's cannula, with spiral spring, for use in plugging the posterior nares.

Passage of a Eustachian catheter.—*Indications.*—As a means of inflating the tympanum—(a) When the ordinary methods, such as politzerisation, have failed; (b) when it is wished to treat one ear alone.

Special instruments.—Eustachian catheter, Politzer's bag, rhinoscopic mirror, and forehead mirror.

Position.—The patient is seated with the back to the light; the surgeon stands or sits directly in front of him.

Operation.—The region of the pharyngeal orifice of the Eustachian tube of the affected side is first examined with the rhinoscopic mirror, in order

FIG. 238.—Method of plugging the posterior nares with Bellocq's sound.—ESMARCH and KOWALZIG.

to ascertain whether there is any physical obstruction to the passage of the catheter.

The Eustachian catheter (Fig. 239) is now taken in the right hand, and passed along the inferior meatus of the nose on the affected side, with the point downwards. The handle is at first lowered, but the instrument is brought to the horizontal as it passes onwards. It is passed backwards till the posterior wall of the naso-pharynx is reached, and then drawn forwards until the point is felt to rise over the posterior free margin of the hard palate. Next, the point is rotated towards the affected side for 90° , and the handle pushed towards the median line. This manœuvre generally causes the point of the catheter to enter the Eustachian tube, though it is sometimes necessary to move it a slight distance along the lateral wall of the naso-pharynx.

The point of the catheter having entered the Eustachian tube, the

tympanum is inflated with Politzer's bag, or any other procedure which is requisite carried out.

Removal of naso-pharyngeal polypus.—Naso-pharyngeal polypi usually grow from the periosteum of that portion of the base of the skull which forms the roof of the naso-pharynx; that is to say, the basilar portion of the occipital bone and the base of the sphenoid.

These polypi may be either simple or malignant in character; when simple, they are usually of the nature of fibro-angiomaticous or fibro-cellular tumours; when malignant, they are always sarcomata.

Care must be taken before commencing an operation on a naso-pharyngeal tumour, to ascertain that it is not a meningocele which has penetrated through the base of the skull.

Indications.—Simple or malignant polypi growing from the base of the skull that can be completely removed.

Special instruments.—Wire snare or electric wire loop cautery, Paquelin's cautery, gag, nasal speculum, forehead mirror, bone forceps, periosteal elevator, Hey's saw, chisel and mallet, sponge-holders, and needles on handles.

Position.—The patient is placed in the dorsal posture with a sandbag underneath the head. The surgeon stands on the right side of the patient, the chief assistant on the left.

Operation.—(a) Through the nose; (b) through the mouth; (c) after temporary resection of the upper jaw.

(a) **Through the nose.**—When the growth is small and has a distinct pedicle, it may be removed in the manner described for simple mucous polypi. The wire loop of an electric cautery is passed along the inferior meatus of the nose, and the mouth being held open with a gag, the surgeon with his left forefinger manipulates the loop round the attached portion of the tumour. The loop is tightened until it includes nothing but the pedicle close to its attachment to the bone. The electric current is now turned on sufficiently to heat the wire to a dull red heat, and the base of the pedicle

FIG. 239.—Eustachian catheter.

cut through. The tumour can now be removed from the naso-pharynx by the fingers, working through the mouth. If severe hæmorrhage follow the removal of the tumour in this manner, it is advisable to pack the naso-pharynx with long strips of gauze.

When the tumour cannot be dealt with by the above method, a more severe operation must be carried out for its removal; the best method is the following:—

(b) **Removal through the mouth.**—*Preliminary preparations.*—If the growth is a very large one, and has extensive

FIG. 240.—Method of surrounding a naso-pharyngeal polypus with a wire before removal.—ESMARCH and KOWALZIG.

attachments to the base of the skull, it is often advisable to perform a preliminary laryngotomy and to plug the upper part of the larynx.

Operation.—1. *Division of palate.*—The mouth being widely opened with a gag, an incision is made, commencing behind the uvula and extending forwards in the middle line of the palate as far as may be considered requisite for the extraction of the tumour. Usually it will be found necessary to prolong this incision for the entire length of the palate. The soft palate and the soft structures covering the hard palate having been completely divided, the periosteum and other structures covering the palatal processes of the palate and superior maxillary bones are

peeled back as far as the gums with a periosteal elevator. Then with a chisel and mallet the exposed part of the hard palate is removed, together with the necessary part of the bony septum of the nose. The mucous membrane covering the upper surface of the hard palate is now divided, by which means the entire naso-pharynx is opened up.

2. *Removal of tumour.*—With the forefinger the pedicle of the tumour is defined, and it is then divided either with the wire loop of the electric canterly, or with scissors, or with a strong rugine, and the entire tumour removed. This part of the operation must be completed as quickly as possible.

3. *Arrest of hæmorrhage and closure of wound in palate.*—After removal of the tumour the hæmorrhage is arrested, either by ligature, or, this failing, by Paquelin's canterly.

The margins of the incision in the soft palate and the soft parts of the hard palate are brought together and fixed in apposition by the insertion of a series of sutures. In the case of vascular tumours it may be necessary to pack the naso-pharynx with tampons of gauze.

(c) **After temporary resection of the upper jaw.**—The skin incision for this operation is similar to the vertical portion of that for the removal of the upper jaw; that is to say, from the middle of the upper lip to the septum of the nose, outwards along the ala nasi, and upwards along the side of the nose to the inner angle of the orbit. The soft parts, however, are not dissected up from the bone. The bony connections of the upper jaw are divided as if for resection, a second incision, over the malar prominence, being made to allow of the section through the frontal process of the malar bone. The upper jaw is then forcibly turned aside and the naso-pharyngeal space thus laid open. The tumour is dealt with as in the preceding operation; when it has been removed and all hæmorrhage arrested, the upper jaw is brought back again to its original position, and fixed by the insertion of a number of sutures.

Removal of adenoid growths from the naso-pharynx.—Adenoid growths of the naso-pharynx may be removed either—(a) through the nose; or (b) through the mouth.

(a) **Through the nose.**

Special instruments.—Ring knife, polypus forceps, or special forceps.

Position.—The patient is anæsthetised and placed in the dorsal position, with the head turned to the right side. The surgeon stands at the right-hand side of the patient's head.

Operation.—The mouth being held open with a gag, the curette,

polypus forceps, or special forceps (Fig. 241) is taken in the right hand, and passed along the inferior meatus of the nose into the naso-pharynx. The forefinger of the left hand is hooked round

the posterior margin of the palate, and then the growths are either scraped away or avulsed with the forceps, the forefinger being used to guide the instrument to the situation of the growths. In this operation care must be taken to scrape away all small pieces of growth from the region of the Eustachian tubes. Hemorrhage is somewhat severe, but usually stops after a short time spontaneously.

(b) Through the mouth.

Instruments.—Löwenberg's forceps, or some modification of it, or Gottstein's curette.

Position.—As in the previous operation.

Operation.—The mouth being held open with a gag, the forceps or curette is taken in the right hand and passed behind the soft palate into the naso-pharynx. The growths are seized by the forceps and forcibly avulsed, or scraped away with the curette. Care must be taken not to seize or to drag away with the forceps any part of the nasal septum, or uvula, or soft palate. This operation is best completed by scraping away

FIG. 241.—Special forceps for removal of adenoids through the nose.—WARING.

with the finger-nail or with an artificial finger-nail whatever portions of the growths have been left behind.

Exploration of the frontal sinuses.—The frontal sinuses are situated between the two tables of the vertical portion of the frontal bone in the region of the superciliary ridges. Their

extent varies ; often they pass outwards as far as the angle of the orbit.

Indications.—(a) Empyema of the frontal sinus ; (b) chronic

FIG. 242.—Ring-shaped knife for removal of adenoid vegetations of naso-pharynx.—MEYER.

FIG. 243.—Gottstein's curette.

FIG. 244.—Forceps for removal of adenoid vegetations of nasopharynx.—WALSHAM.

inflammation of the frontal sinus ; (c) foreign body in the frontal sinus ; (d) polypoid growths from the mucous membrane of the frontal sinus.

Special instruments.—Periosteal elevator, chisel, mallet, bone forceps, sequestrum forceps.

Position.—The patient is placed in the dorsal position. The surgeon stands at the side of the head which is to be operated upon, and the assistant opposite to him.

Operation.—The eyebrows having been shaved off, an incision is made, 2 in. in length, parallel with the supra-orbital margin and half an inch above it, extending outwards from the middle line. This incision divides all the soft structures down to the

FIG. 245.—Position of incision through the bone, in exploration of the frontal sinus of the right side.

bone, including the supra-orbital vessels and nerve and the pericranium.

With the periosteal elevator the periosteum is separated from the bone for half an inch at each side of the incision, and then the margins of the wound are held well apart with retractors. The anterior bony wall of the sinus is next removed with the chisel and mallet, and then the mucous membrane forming the wall of the sinus is incised and the cavity opened. If a new growth, foreign body, or sequestrum is present, it is removed. If the operation is performed for suppurative inflammation of the sinus,

the purulent collection is evacuated. The further treatment of the case depends upon the pathological condition which has been met with; in suppurative conditions it is usually advisable to pass a tube downwards from the sinus through the infundibulum into the anterior part of the middle meatus of the nose, and to partially close the external wound; in cases of new growth or foreign body not associated with suppuration, the external wound is completely closed in the usual manner.

Exploration of the antrum of Highmore.—The antrum of Highmore is situated within the interior of the body of the

FIG. 246.—Drainage of frontal sinus into nose: tube in position.—ESMARCH and KOWALZIG.

superior maxilla, and normally communicates by an aperture with the middle meatus of the nose.

Indications.—The interior of the antrum may require exploration for the following conditions:—

(a) Intractable suppuration, not amenable to ordinary treatment.

(b) Necrosis or sequestrum of part of its bony wall.

(c) Empyema of the antrum.

(d) New growths, cystic or polypoid, simple or malignant, from the mucous membrane.

Special instruments.—Periosteal elevator, small gouge or per-

forator, bone forceps, dental forceps, Volkmann's spoon, drainage tube.

Operation.—The antrum of Highmore may be opened in the following situations :—(1) From the nose ; (2) from the mouth —(a) through the alveolus of a tooth ; (b) through the antero-external wall above the alveoli.

1. From the nose.—Opening of the antrum from the nose is an unsatisfactory operation, since it is impossible in this manner to properly drain the cavity.

The muco-periosteum of the outer wall of the nasal cavity,

FIG. 247.

a. Perforation of antrum from socket of a tooth.

b. Perforation of antrum, through its antero-external wall.

below the inferior turbinate bone, is divided with a scalpel ; and then, with a bone perforator, an aperture is made into the cavity of the antrum. If pus is present it is evacuated, and the subsequent discharge passes into the nose and not into the mouth.

The disadvantage of this operation is, that it does not afford free drainage, owing to the fact that the lower part of the antrum is below the level of the aperture.

2. From the mouth—(a) *Through the alveolus of a tooth.*—If the first or second molar or the canine tooth of the affected side is absent, an incision is made through the gum down to the alveolus, and then with a perforator a hole is bored through

the bone until the cavity of the antrum is reached. When all the teeth are present, the first or second molar should be extracted for the purpose of exposing the alveolus.

(b) *Through the antero-external wall.*—The upper lip having been everted, an incision is made through the mucous membrane and the periosteum, opposite the first and second molar teeth,

FIG. 248.—Antrum perforator.

in the line of reflection from the cheek to the gum. The periosteum is detached upwards and outwards nearly to the lower border of the infra-orbital foramen. The exposed portion of bone is now removed with a chisel and mallet, and the cavity of the antrum laid open.

The operation affords free exposure of the cavity, and enables the surgeon to perform any further manipulation which may be requisite, such as removal of a growth or sequestrum.

CHAPTER XIX.

OPERATIONS UPON THE EAR.

EXTRACTION OF FOREIGN BODIES, OR RETAINED CERUMEN,
FROM THE EXTERNAL AUDITORY MEATUS.

REMOVAL OF GROWTHS FROM THE EXTERNAL AUDITORY
MEATUS—

(a) Polypi.

(b) Exostoses.

INCISION OF MEMBRANA TYMPANI.

EXPLORATION OF MASTOID ANTRUM AND CELLS.

STACKE'S OPERATION.

Extraction of foreign bodies, or retained cerumen, from the external auditory meatus.—It frequently happens that foreign bodies require extraction from the external auditory meatus. This is especially the case in young children.

Special instruments.—Aural syringe, speculum, forehead mirror, aural scoop, and long thin-bladed forceps.

It is not usually necessary to give an anæsthetic in these cases, except when young and refractory children have a foreign body tightly impacted in the auditory canal. In the latter case the administration of an anæsthetic will facilitate the removal of the impacted substance, and diminish the risk of damaging the adjacent parts of the auditory apparatus during the operation.

Operation.—The patient should be seated in a chair in a good light, or, if artificial light is used, it should be behind the affected ear, the surgeon using a mirror attached to his forehead for illumination.

The position and the nature of the foreign body, or plug of retained cerumen, is first made out by examining the meatus through a speculum. If the substance is not firmly impacted, it may be possible to seize it with aural forceps (Fig. 249), and remove it. When it is deeply situated, it is often advisable to syringe out the meatus with warm water, or a solution of boracic

acid. The nozzle of the syringe should be directed slightly upwards, so that the stream of fluid may pass in along the upper wall of the meatus and back along the floor. If this is done carefully, it will suffice, in the majority of instances, for the re-

FIG. 249.—Aural forceps.—CUMBERBATCH.

FIG. 250.—Aural syringe. Three forms of nozzle are illustrated.

FIG. 251.—Aural scoop, for removal of foreign bodies from the external auditory meatus.

moval of plugs of cerumen, or loosely situated foreign bodies. The object of directing the stream along the roof of the meatus is to ensure the fluid passing internal to the slight prominence which is normally met with on the floor of the canal.

If the foreign body cannot be removed with forceps or by syringing, the auricle should be pulled upwards and backwards, and attempt made to pass the "ring scoop" (Fig. 251) beyond the impacted substance, and to extract it by pulling it outwards. Usually this manœuvre will succeed when the other methods have failed. When the obstruction has been removed, the auditory canal is syringed clean, and a small plug of aseptic wool placed in the meatus.

Removal of growths from the external auditory canal.—(a) *Polypi*.—Polypi situated in the external auditory canal may arise from the walls of the canal, from the membrana tympani, or from the mucous membrane or the periosteum which lines the tympanic cavity. The commonest seats of origin are the external aspect of the membrana tympani and the mucous membrane of the tympanic cavity.

These polypi are usually of the nature of simple fibrous or cellular tumours. Only in very rare instances are they malignant.

Special instruments.—As for the preceding operation, with the addition of an aural snare.

Operation.—The external auditory canal should first be syringed out with a dilute antiseptic solution, and then the nature of the growth and its point of attachment made out. The aural snare (Fig. 252) is next taken, and the wire loop passed around the tumour until its attached portion or pedicle is surrounded. The wire is then tightened until the pedicle is constricted. If the growth is attached to the wall of the canal, or to the membrana tympani, a

FIG. 252. — Wire snare for removal of polypi from external auditory meatus or tympanic cavity.

sharp pull is made on the snare, by which means the polypus together with its attachment is forcibly pulled away. If, however, it is attached to the mucous membrane of the tympanic cavity, the wire loop should be gradually tightened until the pedicle has been cut through. The polypus is then removed.

When the growth has the latter-mentioned detachments, it is not advisable to remove it by forcible avulsion, otherwise one or more of the small bones of the tympanum may be removed along with it.

When the polypus has been removed, the auditory canal is syringed out and then examined through the speculum. If any other growths are discovered, they are removed in a similar manner. In the case of very small polypi, it may not be possible to get hold of them with the snare. In this case they should be destroyed with the electric cautery, care being taken not to injure the inner wall of the tympanic cavity, on account of the liability of damage to the internal ear.

(b) *Exostoses*.—Exostoses of the external auditory canal occasionally occur. They chiefly affect the floor and the posterior wall. Usually they are of the nature of “ivory” exostoses. No attempt should be made to remove them, unless they are giving rise to severe symptoms, owing to complete blocking of the external auditory canal. If it is decided to remove them, the best method of operation appears to be by the employment of the dental engine or electric surgical engine, the attached base being cut through. The bone at the base is said to be softer than that at the free extremity. Care must be taken not to splinter the petrous portion of the temporal bone, or damage any of the important anatomical structures in the neighbourhood.

Incision of the membrana tympani.—*Indications*.—This operation may be necessary in the following conditions:—

(a) Accumulation of pus within the tympanic cavity.

(b) The presence of polypoid growths attached to the mucous membrane of the tympanic cavity, the membrana tympani being intact.

(c) Necrosis of one or more of the auditory ossicles.

Special instruments.—Aural speculum, forehead mirror, special knife, long thin-bladed aural forceps.

Position.—The patient and operator are seated as for the removal of a foreign body

FIG. 253.—Knife for incision of membrana tympani.

Operation.—The external auditory canal is syringed out so as to remove all secretion, and then dried with plugs of wool. The speculum is introduced, and the most bulging portion of the membrane ascertained. The knife (Fig. 253) is passed through the speculum, and an incision made in the bulging portion of the membrane, and if possible at its lower part. If the operation is done for the evacuation of a collection of pus, this will at once exude. If for the removal of a polypus or a sequestrum, the subsequent procedure is similar to that mentioned in the preceding operation.

It is advisable to paint the tympanic membrane with a 10 per cent. solution of cocaine before an incision is made through it.

FIG. 254.—Opening of mastoid antrum and mastoid cells. *a.* Position of external incision.

Exploration of the mastoid

antrum and cells.—On account of the close communication which exists between the air-containing spaces within the mastoid process (mastoid antrum and mastoid cells) and the tympanic cavity, and the frequency with which the latter space is the seat of suppurative affections, it often happens that the surgeon is called upon to explore the interior of the mastoid cells, owing to an extension of the suppurative process from the tympanum.

Indications.—(*a*) Acute suppurative affections of the mastoid process.

(*b*) Chronic inflammatory affections of the mastoid, associated with the formation of a collection of pus or a sequestrum.

(*c*) Cholesteatomatous swellings or collections of secretion within the mastoid process, especially in the antrum.

Special instruments.—Periosteal elevator, grooved chisel, mallet, small Volkmann's spoon, fine sequestrum forceps.

Position.—The patient is placed in the dorsal posture, with a pillow underneath the head, and the head turned towards the sound side. The surgeon stands on the affected side and his assistant opposite to him.

Operation.—An incision a little over 2 in. in length is made parallel with and immediately behind the free border of the auricle, commencing above and terminating near the apex of the mastoid

process. This incision divides everything down to the bone, including the periosteum. Some small branches of the posterior auricular artery will usually require ligature. Next, the soft tissues are lifted up from the bone with a periosteal elevator, as far as the posterior border of the meatus, and backwards for a short distance if necessary. The assistant pulls the auricle well forwards, and at the same time retracts the margins of the incision. The operator next takes the chisel and mallet, and removes the external table of the mastoid process, the portion of bone removed corresponding to the circle in Fig.

FIG. 255.—Position of the incision through the bone, in exploration of the mastoid antrum and cells.

255. In the deeper part of the operation, it is advisable to manipulate the chisel or gouge with the hand alone. By this means the region of the mastoid antrum and the upper mastoid cells will be laid bare, and can be explored. Any collection of pus, cholesteatomatous material, or sequestrum which may be present, will by this means be partially or entirely exposed. If the former, more bone must be chiselled away in the direction of the diseased part, and then all diseased tissue or abnormal collections can be removed. If necessary, the incision in the bone can be prolonged upwards and forwards into the tympanic cavity, forwards into the outer and posterior wall of the auditory

canal, or backwards and downwards into the lower groups of mastoid cells.

Care must be taken not to injure the facial nerve as it lies in the aqueduct of Fallopius, posteriorly and inferiorly to the antrum, and not to wound the lateral sinus or any of the other cranial contents.

All diseased tissue having been removed, the interior of the wound is irrigated with an antiseptic solution, and then packed with a strip of gauze. The upper part of the skin incision is closed with sutures, and the lower left open for drainage and to enable irrigation to be carried out at each change of the dressings, if necessary.

Another method of completing the mastoid operation is frequently adopted, and, after the name of the originator, has been called Stacke's operation.

Stacke's operation.—The external incision is made in a manner similar to that described in the previous operation, and the necessary surgical treatment of the mastoid antrum carried out. Next, the concha is separated from its cartilaginous and bony attachments, and the cavity of the antrum with its tympanic and posterior connections thus made to communicate freely with and open into the external auditory meatus. The margin of the concha, which was previously-attached to and formed part of the wall of the external auditory meatus, is now turned backwards and united by the insertion of sutures to the posterior margin of the original post-auricular incision. Next, the margins of this post-auricular incision are

brought into apposition and fixed by sutures. By these measures the antral and tympanic cavities and their prolongations are made to communicate directly and be continuous with the external auditory meatus, and the incision behind the ear is completely closed.

The after-treatment is carried out entirely through the aperture of the external auditory meatus. At a later period, skin flaps may with advantage be applied to the remaining portion of the antro-tympanic wall. This will accelerate convalescence, and lessen the formation of excessive granulations and subsequent undue cicatrisation.

FIG. 256.—Grooved chisel for opening mastoid process in mastoid disease.

CHAPTER XX.

OPERATIONS ON THE TONSILS.

INCISION OF A TONSILLAR ABSCESS.

REMOVAL OF THE TONSIL.

(a) For simple enlargement.

(b) For malignant growth.

(1) Operation through the mouth.

(2) Operation through an incision in the neck.

Anatomical position of the tonsil.—The tonsil is situated between the anterior and posterior pillars of the fauces at the side of the base of the tongue, and beneath the angle of the jaw. The internal carotid artery is one-half to three-quarters of an inch behind and to its outer side, and separated from it by connective tissue and that part of the deep cervical fascia which forms the carotid sheath.

Incision of a tonsillar abscess.—Abscess of one tonsil is a common affection, and frequently the surgeon is called upon to make an incision into it, in order to evacuate the contained pus. This is effected as follows:—An ordinary tenotomy knife is taken, and around the blade is wrapped a strip of strapping, in such a manner that only half an inch of the cutting portion, at the point, is left bare. Next, the surgeon directs the patient to open the mouth, and, by a small stab and cut, makes an opening in the wall of the abscess. The pus is evacuated into the mouth, and is spat out by the patient. The surface of the tonsil may be painted with a 10 per cent. solution of cocaine a short time before the operation, if it is wished to minimise the pain.

After the pus has been evacuated, the pharynx should be frequently washed out with an antiseptic solution.

Removal of the tonsil.—(a) For simple enlargement; (b) for malignant growths.

(a) *For simple enlargement.*—This is best effected with some

form of guillotine. Fig. 257 is an illustration of an instrument which is very suitable for this purpose.

The patient is seated in the upright position, whilst an assistant, standing behind, holds the head. When the tonsil is being removed, the assistant is directed to press it inwards by placing his finger immediately behind the angle of the jaw. The guillotine is passed into the mouth, and the tonsil made to protrude through the aperture at its extremity. With a sharp cut it is removed. Both tonsils can be removed simultaneously, by using a guillotine with each hand. This, however, is only necessary in the case of children.

The regions of the tonsils should be painted with a 10 per cent. solution of cocaine a short time before removing them.

(b) *For malignant growths.*—The primary malignant growths which affect the tonsil are epitheliomata and sarcomata, the latter being the more common.

The tonsil, when affected by a malignant growth, may be removed either by an operation carried out through the mouth, or through an incision in the superior and lateral portion of the neck. The former operation is suitable for those

FIG. 257.—Mackenzie's tonsil guillotine.

cases in which there is not extensive enlargement of the neighbouring lymphatic glands, and the latter for cases in which there is infiltration of the lymphatic glands in the region of the angle of the jaw. Involvement of the lymphatic glands tends to occur very early in malignant disease of the tonsil. Few, if any, of the cases in which it has taken place have been cured by an operation.

Operation through the mouth.—*Special instruments.*—Blunt-pointed scissors, gag, volsellum forceps, and laryngotomy tube.

Position.—The patient is placed in the dorsal position, with the head supported by a firm pillow; the surgeon stands on the affected side of the head and his assistant opposite to him.

Preliminary laryngotomy.—In most cases it is advisable to perform a preliminary laryngotomy, and then to plug the upper aperture of the larynx with a marine sponge. This will prevent blood passing downwards into the respiratory passages.

Operation.—An incision is made horizontally backwards from the angle of the mouth, on the affected side, to the anterior border of the masseter muscle. The facial artery is cut across in this procedure, and its two ends must be secured and tied. The flaps of the cheek are held aside, and the tongue drawn forwards and to the opposite side. If necessary, a strong silk ligature is passed through the tongue and given to an assistant to hold, in order to exert traction when required.

The soft palate is divided well beyond the limits of the growth with the scissors, and the cut carried backwards into the walls of the pharynx, care being taken to make the incision some distance from the margins of the diseased tissues. The tonsil is next seized with volsellum forceps (Fig. 258), and dragged

FIG. 258.—Volsellum forceps.

forwards, the tissues which attach it to the wall of the pharynx being cut through with the scissors. By this means the tonsil with the malignant growth is removed. In some cases of sarcomata it will be found that the growth shells out of a sheath. Unfortunately, however, in these cases, recurrence is very prone to occur, and it is better to cut wide of the disease, if it can be done with safety, than to trust to shelling it out of the capsule of connective tissue. All hæmorrhage from the area of operation is arrested, and the margins of the incision in the cheek united by the insertion of a series of interrupted sutures. The laryngotomy tube can usually be taken out at the end of the operation. If, however, there is much bleeding, it will be advisable to pack the wound in the pharynx with strips of aseptic gauze, and delay the removal of the laryngeal tube for a day or two.

Operation through an incision in the neck.—Several varieties of operation by this method have been proposed. The incision

is made along the anterior border of the sterno-mastoid of the affected side, commencing above at the lobule of the ear, and extending downwards to the great cornu of the hyoid bone. In most cases it is necessary to remove a portion of the lower jaw, or at least to saw it through and turn it aside.

The success which has followed these operations has been very slight, and it may be doubted whether they are justifiable. In those cases with extensive enlargement of the lymphatic glands it is probably better to remove the primary growth through the mouth, by the method described above, and to deal with the affected lymphatic structures through a second incision in the neck.

CHAPTER XXI.

THE LIGATURE OF ARTERIES.

Indications for operations upon arteries.—The following are the most important clinical conditions which may necessitate the ligature of an artery :—

Aneurysm.

Primary and secondary hæmorrhage.

Preparatory to the removal of important organs, in order to avoid excessive hæmorrhage.

Certain cases of pulsating tumours—for example, ligature of the internal carotid for a pulsating tumour of the orbit.

Certain cases of malignant tumours which have undergone ulceration, and are liable to hæmorrhage, or in order to arrest their growth.

The position of the patient and the operator.—The positions of the patient and the surgeon depend upon the situation of the artery which it is proposed to ligate. The patient is placed in a position which permits the exact demarcation of the blood vessel, and allows of easy access to it ; whilst the surgeon stands, in the majority of instances, at that side of the patient which is to be operated upon, his chief assistant being on the opposite side.

Instruments.—The instruments which are required for the ligature of arteries are—

1. *Knife.*—An ordinary scalpel, not too large, is best for the purpose. Some surgeons advise that the skin incision should be made with a large one, and the deep dissection with a smaller one ; this, however, is not necessary.

2. *Dissecting forceps.*—These should be of medium size, and not too sharp at the points ; two pairs are requisite. When a deep artery is being ligatured, it may be advisable to have in addition a long pair of forceps with fine serrated points, in order to seize the sheath of the artery while opening it ; but this is not usually necessary, as the ordinary dissecting forceps can generally be used for this purpose.

3. *Retractors*.—The kind which is most useful depends upon the artery which is being ligatured. Thus, for the iliac arteries,

or whenever there is a deep wound, wide retractors are the best; while, when the vessel is superficial, blunt hooks serve the purpose. In the case of deep wounds it is better to have both blunt hooks and broad and deep retractors.

4. *Pressure forceps*.—These are for the arrest of hæmorrhage from the margins of the wound. Several pairs are requisite. When operating upon large arteries, it is advisable to have an elastic tourniquet at hand; this may be found necessary for the control of serious and sudden hæmorrhages.

5. *Aneurysm needle*.—An ordinary curved needle is sufficient in most cases, but for deep-seated arteries, such as the iliacs, a double-curved needle will be the most useful. Two of these should be at hand, one curved to the right and the other to the left.

6. *Ligature and suture material*.—This should be of two thicknesses, one for the vessel itself, and the other for the ligation of any small vessels which may be cut during the operation, and for sewing up the wound afterwards. Silk is the best ligature material, but many surgeons prefer chromicised catgut. For the external wound, salmon-gut will

FIG. 259.—Ligature of arteries. Aneurysm needles with a double curve, one to the right and the other to the left.

often be found the best.

7. *Needles*.—An ordinary medium-sized half-curved or straight needle is used for sewing up the external wound. When it is

necessary to introduce a tier of deep sutures, a fully-curved needle and a needle-holder will be found requisite.

General method of operating.—The operation for the ligation of an artery in its continuity consists of several distinct stages, namely—

(a) *The skin incision.*—The anatomical position of the artery is determined according to the directions which are given in the text-books of anatomy. Great care must be taken in placing the patient in the correct attitude, so as to avoid the possibility of a mistake being made. When this has been done, an incision is made through the skin, usually in the line of the blood vessel, varying in length according to the size of the artery and its depth from the surface of the body. Thus, in ligation of the radial at the wrist, an incision of $1\frac{1}{2}$ in. is quite sufficient, whilst for the first portion of the axillary artery it must be 4 in. long. As a general rule, it is advisable to make a moderately long incision, since no harm can be done by this, and the dangers of working in a confined space are avoided. In operations on the face or the exposed parts of the extremities, it is better to avoid making too long an incision, on account of the resulting scar being visible. Whilst making the incision through the skin, the knife may be held in either the “dinner-knife” or the “dissecting” position (Figs. 28 and 26). In the case of small incisions it is advisable to adopt the latter method, and for long incisions the former. The blade of the knife should be sloped whilst making the main part of the wound, and, finally, it should be brought out vertically, so as to avoid “tailing,” and to ensure that the wound is of equal depth for its entire extent. Care must be taken to avoid damage to any superficial veins when the skin incision is made; but if one of these structures cannot be easily avoided, it must be cut through, and its two extremities tied.

(b) *The division of the deep fascia.*—The deep fascia can, in most parts of the body, be recognised as a thin dense lamina of fibrous tissue immediately underneath the fatty layer. It is divided for the entire extent of the incision, and by this means the muscular strata are exposed. It is important to recognise the deep fascia, especially in fat people or when operating upon

FIG. 260.—Form of retractor suitable for use in exposure of an artery.

the dead body, since all arteries whose ligature may be required lie underneath this layer.

(c) *The separation of the muscles or tendons, and exposure of the artery.*—When the deep fascia has been divided, its margins are drawn aside and separated with retractors, so as to fully expose the muscular layer. In most cases the space between two particular muscles has to be recognised in order to find the blood vessel. This separation is best effected with the finger or the handle of the scalpel, preferably the former in most cases. The intermuscular septum between two muscles is said to be indicated by a white line, which is caused by a localised thickening of the fascia, but this sign cannot be depended upon. It is

FIG. 261.—Ligature of arteries. Method of opening the sheath of an artery, before an aneurysm needle is passed.

better to trust to the finger, and to feel for a slight depression along the line of separation between the two muscles. The muscles are held apart with retractors, and care is taken to make the wound of the same depth throughout. When the muscles have been separated, the artery can usually be recognised lying at the bottom of the wound, and often accompanied or surrounded by its *venæ comites*, or having a nerve in close relation to it. In the living person the artery can usually be distinguished by its pulsations, but care must be taken not to mistake a transmitted pulsation for the true pulsation of the vessel itself.

(d) *The opening of the sheath of the artery and the passage of*

the needle and ligature.—When the artery has been exposed, its sheath is opened, so as to permit of the easy passage of the ligature, and to avoid the enclosure of or injury to any important adjacent anatomical structure by the ligature. A small fold of the sheath, transverse to the long axis of the artery, is picked up with fine forceps and incised with a scalpel, an aperture about one-third of an inch in length being made in it (Fig. 261). The aperture should lie over the centre of the exposed portion of the vessel, or, when there is only one accompanying vein, somewhat to the side furthest away from that structure. Thus, in the case of the common carotid artery, it is advisable to make the incision into the sheath well on the inner side, so as to avoid wounding the internal jugular vein, which overlaps it to a considerable extent. When the incision into the sheath is being made, the sheath itself should be lifted quite away from the vessel for a distance of about one-third of an inch by means of dissecting forceps. One margin of the incision in the sheath is seized with the forceps, and then the point of the aneurysm needle is gently insinuated round the artery for half its circumference. Next, the other margin of the sheath is seized and the point of the needle passed round in the opposite direction, until the sheath is separated for the entire circumference. When this has been done, the margin of the sheath which lies adjacent to the accompanying vein, or other important anatomical structure, is held with forceps, and the aneurysm needle passed around the artery, care being taken not to lift up the vessel from its bed more than is absolutely necessary. The aneurysm needle is always passed around an artery in an unthreaded condition, and then threaded with a ligature (usually silk), and withdrawn. If the sheath of the artery has been well opened and separated,

FIG. 262. — Ligature of arteries. Simple curved aneurysm needle.

and the needle is kept close to the wall of the vessel as it is passed, there is very little risk of doing any injury to neighbouring structures. The ligature is tied with a "reef-knot," at right angles to the long axis of the vessel. The knot is made gradually, and no sudden tension or pull exerted. During the tying of the ligature the artery must not be lifted up in the wound; this is prevented by making the extremities of the two forefingers meet immediately above the artery upon the site of the knot, and exerting tension from the knuckles. The ligature should be tied tightly enough to rupture the inner coats of the vessel. The ends of the ligature are finally cut short, and the knot allowed to retract into the interior of the sheath.

Some surgeons prefer to tie the artery in two places, and then to divide the vessel between the ligatures. This, in my opinion, is not necessary, and in certain regions it is dangerous. This is especially so in connection with the third part of the subclavian.

(e) *The closure of the external wound.*—In most cases of ligature of an artery, it is not necessary to divide any muscles, and hence, when the retractors are removed, the structures resume their normal position; but if it is found requisite to divide a muscle or muscles, or if the deeper parts of the wound do not come into good apposition, it is necessary to unite these with a tier of deep sutures. The margins of the incision in the skin and fasciæ are then united by the insertion of interrupted sutures, and the ordinary aseptic dressings applied.

EXPOSURE AND LIGATURE OF INDIVIDUAL ARTERIES.

The innominate artery.—The innominate artery is a large branch of the thoracic aorta, given off from the convexity of the arch opposite to a point situated slightly to the right of the middle of the manubrium sterni. From its origin, it passes upwards and to the right to the base of the neck, where it terminates by dividing into the right common carotid and right subclavian arteries.

Its course is represented on the surface of the chest by drawing a line from a point immediately to the right of the central point of the manubrium sterni to the upper border of the sterno-clavicular articulation of the right side. The vessel usually measures about $1\frac{1}{2}$ in. in length, and gives off no branches in its course, though, in exceptional cases, it may give origin to the thyroidea ima.

The innominate artery lies behind the manubrium sterni, the origins of the right sterno-hyoid and sterno-thyroid muscles, and

the remains of the thymus gland; whilst at its origin it is crossed by the left innominate vein, and for its entire course it is overlapped from the outer side by the right innominate vein. To the right lie the right innominate vein, the right vagus nerve, and the parietal layer of the right pleura and the right phrenic nerve; on the left, the inferior thyroid veins, the remains of the thymus gland, and the commencement of the left common carotid artery; behind, it is in relation with the thoracic portion of the trachea and the right pleural sac. The height at which the vessel divides varies; sometimes it is lower than usual, but only rarely does it divide in the neck above the clavicle.

Position.—The patient is placed in the dorsal position, near the right side of the table, the shoulders are raised, the right arm pulled downwards and fixed in that position, the head extended and rotated towards the left.

The surgeon stands opposite the right shoulder, the chief assistant opposite to him, and a second assistant on the left side of the head.

Operation.—An angular incision is made, one limb of which extends along the upper border of the inner third of the clavicle, and the other limb along the anterior border of the sterno-mastoid muscle. Each part of the incision is about 3 in. in length. The skin, superficial fascia, and deep cervical fascia are divided along both parts of the incision, and the muscles exposed. The outer and lower portion of the sterno-mastoid and the sterno-hyoid and sterno-thyroid muscles are divided close to their attachments to the clavicle and sternum, and a flap turned upwards and outwards. The deep cervical fascia which lies behind the muscles is now laid bare, and the carotid sheath can be seen in the inner portion of the wound. Care must be taken, when turning up the flap, not to injure the anterior jugular vein as it passes behind the inner part of the sterno-mastoid. The carotid sheath is opened in the lower part of the incision, and the common carotid artery traced downwards and inwards until the innominate artery is well exposed. When this has been done, it is separated from its sheath as carefully as possible, so as to avoid injury to the veins in the immediate neighbourhood. The right innominate vein may be considerably dilated and overlap the artery; the left innominate vein may cross higher than usual, and appear in front of the vessel in the upper part of its course; and the inferior thyroid veins may be very large and overlap the innominate artery from the inner side. When the artery has been separated from its connections, the aneurysm needle is passed from the outer side,

care being taken to avoid puncture of one of the veins, injury to the pleura, or enclosure of the right vagus nerve. A strong silk ligature is probably the best form of material to tie the vessel with. Some surgeons advise that the common carotid and vertebral arteries should be ligatured as well, so as to diminish the risk of secondary hæmorrhage. When this has been done, the wound is closed.

When the innominate artery divides at a moderately high level, or when the patient has a long and thin neck, it will be found that the ligature of the vessel can be effected through an incision along the anterior border of the sterno-mastoid.

Collateral circulation.—(a) Intercostal branches of aorta with similar branches from the superior intercostal branch of the subclavian; (b) internal mammary, by means of its superior epigastric branch, with the deep epigastric branch of the external iliac, and by means of its musculo-phrenic branch with the lower five or six intercostal branches of the thoracic aorta; (c) the aortic intercostals of the third to the sixth space with thoracic branches of the axillary artery (long thoracic, pectoral branches of acromio-thoracic, and subscapular); (d) communications between various branches of the external and internal carotid arteries on one side, and similar branches on the opposite side.

The common carotid artery.—This vessel on the right side is given off from the innominate artery, and on the left from the arch of the aorta between the innominate and the left subclavian. The thoracic portion of the left artery is not suitable for the application of a ligature. The course of the vessel in the neck is marked out by drawing a line from the sterno-clavicular joint upwards to a point midway between the angle of the jaw and the apex of the mastoid process when the head is turned slightly towards the opposite side. The vessel divides at the upper border of the thyroid cartilage. It is enclosed within a sheath of the deep cervical fascia, and opposite the cricoid cartilage it is crossed by the anterior belly of the omo-hyoid muscle. That portion of the vessel which lies above the omo-hyoid is covered only by the deep cervical fascia, the inner border of the sterno-mastoid, the superficial fascia, platysma, and skin; whilst that below this muscle has in front of it, in addition to the above structures, the sterno-hyoid and sterno-thyroid muscles. Within the sheath of the artery lie the internal jugular vein on the outer side, and the vagus nerve behind and between the two. Each structure lies within a special compartment of the sheath. Occasionally, the descendens cervicis nerve is found in front of

the artery within the sheath, but usually it lies outside. The carotid tubercle of the sixth cervical vertebra lies immediately behind the artery. The relative position of the artery to the adjacent structures is shown in Fig. 263.

A ligature may be applied either above or below the omo-hyoid muscle, preferably above, in the majority of cases, on account of the superficial situation of the vessel at this level.

Ligature of the common carotid artery above the omo-hyoid.—*Position.*—The patient is placed in the dorsal position, with the shoulders slightly raised, and the head turned somewhat to the opposite side.

The surgeon stands on the affected side of the patient, and the assistant on the opposite side.

Operation.—An incision is made in the line of the artery,

3 in. in length, and so situated that its centre is opposite the upper border of the cricoid cartilage. The skin, the superficial fascia containing branches of the superficial cervical nerves and possibly tributaries of the external jugular vein, and the deep fascia are divided in the line of the incision. By this means the sterno-mastoid muscle is exposed. The inner border of this is next defined and retracted outwards. The anterior belly of the omo-hyoid will then be seen crossing upwards and inwards. It is pulled downwards with a retractor, and then the carotid sheath will be visible, and lying upon it may be seen in many cases the descendens cervicis nerve. This nerve is pulled outwards, and the sheath opened on the inner side, so as to avoid puncture of the internal jugular vein. The artery is separated

FIG. 264.—Ligature of common carotid artery. Position of patient and line of external incision. Dotted line indicates the clavicle.

from its sheath for a short distance in the usual manner, and the needle is passed from without inwards, care being taken not to include the vagus nerve or the sympathetic cord which lies immediately behind the sheath. During the passage of the needle and the separation of the sheath, the vessel should not be disturbed more than is necessary. The superior and middle thyroid veins usually cross the front of the carotid sheath, in which case they are drawn upwards, or ligatured in two places and divided between.

Ligature of the common carotid below the omo-hyoid.—

Position.—As for ligature of the vessel at a higher level.

Operation.—An incision from 3 to 4 in. long is made in the line of the artery, commencing, below, a short distance above the sterno-clavicular joint, and extending upwards to the level of

the crico-thyroid membrane or the lower portion of the thyroid cartilage (Fig. 264). The skin, the superficial fascia containing the supra-sternal branch of the cervical plexus and possibly the anterior jugular vein, and the deep fascia, are incised, and the anterior border of the sternal head of the sterno-mastoid laid bare. This muscle is drawn outwards, the attachment to the sternum being divided if requisite, and by this means the sterno-hyoid and sterno-thyroid muscles are exposed, and possibly, in the upper part of the incision, the omo-hyoid. The sterno-hyoid and sterno-thyroid muscles are drawn inwards, their fibres being cut across if necessary, and the omo-hyoid is retracted upwards. One or more inferior thyroid veins may be met with at this stage, and give rise to trouble. If seen they must be drawn inwards, or ligatured in two places and divided between. The carotid sheath, which contains the artery, is now exposed. The sheath is opened on the inner side, and the needle passed from without inwards. On the left side the internal jugular vein lies somewhat anterior to the artery, and may prove a source of trouble.

Collateral circulation.—(a) The superior thyroid with the inferior thyroid; (b) the occipital with the deep cervical and the transverse cervical; (c) the branches of the external carotid with similar branches from the opposite side; (d) branches of the external carotid with branches of the vertebral; (e) the various communications at the circle of Willis.

The external carotid artery.—This vessel is one of the terminal branches of the common carotid, and is given off at the level of the upper border of the thyroid cartilage. Its course is approximately marked out by prolonging upwards the line of the common carotid. The artery terminates immediately below and internal to the condyle of the lower jaw, by dividing into the internal maxillary and superficial temporal arteries. In its course it gives origin in front and internally to the superior thyroid, the lingual and the facial arteries; posteriorly it gives off the posterior auricular and occipital arteries, and from its deep aspect the ascending pharyngeal. The superior thyroid is given off immediately above the commencement, the lingual opposite the greater cornu of the hyoid, the occipital and facial at a slightly higher level, and the ascending pharyngeal usually at about the same level. The posterior auricular artery arises a little above the occipital. The superior thyroid may be given off from the common carotid, whilst the lingual and facial not infrequently arise by a common trunk. The artery at its commencement is somewhat superficial, being

covered by the skin and fasciæ and overlapped by the sternomastoid. The hypoglossal nerve crosses the vessel about 1 in. beyond its origin, and the posterior belly of the digastric muscle at a slightly higher level. The artery is generally ligatured below the digastric at a point between the origins of the superior thyroid and the lingual arteries.

Position.—As for ligature of the common carotid.

Operation.—An incision about 3 in. long is made in the line of the vessel, the central point of the incision corresponding to the apex of the greater cornu of the hyoid bone (Fig. 265). If this cannot be felt, the incision extends from opposite the middle of the thyroid cartilage to the angle of the lower jaw. The skin and fasciæ, with the platysma and any superficial veins, are divided and the external surface of the sternomastoid exposed. The internal border of this structure is defined, and the muscle drawn outwards. In the upper section of the wound the posterior belly of the digastric muscle is sought for, together with the hypoglossal nerve. When found, these structures are retracted into the upper portion of the incision. The apex of

FIG. 265.—a, Line of incision for ligature of external and internal carotid arteries.

the greater cornu of the hyoid bone is next laid bare, together with that portion of the external carotid artery which lies between the points of origin of the superior thyroid and lingual arteries. This part of the vessel may be surrounded by veins, in which case they are drawn aside and the artery separated from the adjacent structures. The aneurysm needle is then passed from without inwards, care being taken to avoid the superior laryngeal nerve, which lies posterior to the vessel. In some cases it is necessary to ligature the exposed part of the external carotid and the separate branches as well, when they are given off in immediate proximity to the point of application of the main ligature.

Collateral circulation.—This is similar to that given in con-

nection with ligature of the common carotid, with the exception of the anastomosis between the superior and inferior thyroid arteries.

The superior thyroid artery.—The ligature of this artery is carried out through an incision similar to that described for the external carotid. The external carotid is defined and traced downwards until the superior thyroid is exposed.

The lingual artery.—The lingual artery is a branch of the external carotid, given off opposite the apex of the greater cornu of the hyoid bone. Its course may be divided into three parts, the first extending in an oblique direction from its origin to the outer margin of the hyoglossus; the second is horizontal in direction and lies underneath the hyoglossus; whilst the third ascends and is situated beneath the tongue.

The first part is superficial, and has the same coverings as the external carotid; the second lies deeper upon the middle constrictor of the pharynx and the genio-hyoglossus and behind the hyoglossus, parallel with the upper border of the greater cornu of the hyoid bone, but at a slightly higher level. The cornu of the hyoid bone is the guide to the vessel in this part of its course. The hyoglossus muscle separates the artery from the hypoglossal nerve, which, however, lies at a higher level, and also from the lingual (ranine) vein. The artery may be ligatured in either the first or the second part of its course, usually the latter.

When a ligature is applied to the vessel in the first part of its course, the operation is similar to that for ligature of the external carotid.

Ligature of the lingual artery beneath the hyoglossus.—*Position.*—The patient lies in the dorsal position near the end of the table, with the shoulders raised, the head turned towards the opposite side, and held in position by an assistant.

The surgeon stands on the side which is to be operated upon, the chief assistant on the opposite side, and a second assistant near the operator. The second assistant holds the head in position, and retracts the digastric tendon at the proper time.

Operation.—A curved incision is made, commencing half an inch outside and a short distance below the symphysis menti, and extending downwards to the tip of the great cornu of the hyoid bone, and then upwards to a point a little below and in front of the angle of the lower jaw (Fig. 266). This incision divides the skin, the superficial fascia with the platysma, and the deep fascia for its entire length. When the deep fascia has been fully divided, the lower margin of the submaxillary salivary gland is

sought for and hooked upwards with a retractor. Next, the intermediate tendon of the digastric muscle is exposed, as it lies in the lower portion of the wound. When defined, it is drawn downwards with a blunt hook, and so held by the second assistant (Fig. 267). The fibres of the hyoglossus muscle are now visible in the angle between the two bellies of the digastric, and in many cases the hypoglossal nerve or the lingual vein is seen lying upon this muscle. If these latter structures are exposed, they are retracted upwards out of the field of operation, and then with the tip of the finger the upper border of the greater cornu of the hyoid bone is felt for. When this has been defined, the fibres of the hyoglossus are cut through about one-third of an inch above the hyoid. A connective tissue or fascial plane will soon be met

FIG. 266.—Ligature of lingual artery. *a*. Line of external incision.

with when the fibres of the muscle have been divided, and in this tissue will be found the lingual artery. Care must be taken not to overlook this plane, otherwise the fibres of the middle constrictor may also be divided, and the incision made to communicate with the cavity of the pharynx. When the artery has been exposed, it is separated for a short distance from its surroundings, and the needle passed from above downwards.

The facial artery.—This vessel is a branch of the external carotid given off a short distance above the apex of the greater cornu of the hyoid bone; or it may be given off along with the lingual by a common trunk. From its origin the artery passes upwards, lying in a deep groove in the submaxillary gland, and then over the horizontal ramus of the lower jaw, about a third

of the distance from the angle to the symphysis, and immediately in front of the masseter muscle. Above this point it passes onwards to the tissues of the face. The vessel can be felt pulsating as it passes over the ramus of the jaw, and also just beyond its point of origin in the neck.

In the latter position the operation is similar to that for ligature of the external carotid.

FIG. 267.—Ligature of lingual artery.

Ligature of the facial artery as it lies upon the lower jaw.—*Position.*—The patient is placed in the dorsal position, with the head resting on a pillow and turned over towards the opposite side. The operator stands on the affected side of the head, and the assistant opposite to him.

Operation.—The anterior border of the masseter and the situation of the vessel on the jaw are first defined; then the

skin of the neck and face is drawn upwards, so that the resulting scar may be under the jaw, and an incision 1 in. in length is made parallel with the inferior margin of the jaw, and having its central point opposite the vessel (Fig. 268, *a*). The skin, superficial fascia, and platysma are divided, and then the artery will be exposed as it lies upon the bone. The vessel is separated from its accompanying vein, which lies posterior to it, and the needle is passed from behind forwards.

The superficial temporal artery.—This artery is one of the terminal branches of the external carotid, given off in the substance of the parotid gland. It passes upwards over the zygoma and superficial to the temporo-maxillary joint, to supply the scalp. It may be ligatured where it lies upon the zygoma, in front of the external auditory meatus.

Position.—As for ligature of the facial artery.

Operation.—An incision $1\frac{1}{2}$ in. in length is made along the line of the vessel, a short distance in front of the auditory meatus, the central point of the incision corresponding to the zygoma (Fig. 268, *b*). The skin and fasciæ are divided, when the artery will be exposed lying upon the bone, surrounded by its venæ comites, and having the auriculo-temporal nerve immediately behind it.

FIG. 268.—Ligature of facial and superficial temporal artery.

- a.* Position of incision for facial artery.
b. " " " superficial temporal artery."

The vessel is carefully separated from the nerve, and from its veins if possible, and the needle passed from behind.

The occipital artery.—This is a branch of the external carotid, arising from this vessel on its posterior aspect and a little above the level of the greater cornu of the hyoid bone. It first passes upwards in the neck, and then almost horizontally backwards, between the mastoid process and the lateral mass of the atlas, lying in a groove in the mastoid portion of the temporal bone, and finally ascends vertically to the scalp.

It may be ligatured in the anterior triangle of the neck, or as it lies in relation with the mastoid portion of the temporal bone.

In the first case the operation is similar to that for the ligature of the external carotid.

Ligature of the occipital artery as it lies in the mastoid region.—*Position.*—The patient is placed on the sound side, with the head resting on a pillow and turned well towards the opposite side. The surgeon stands on the affected side and the assistant opposite to him.

Operation.—An incision about 2 in. in length is made, which commences, below, at the posterior border of the mastoid process, and immediately above its apex, and extends upwards to a point midway between the posterior border of the base of the mastoid and the external occipital protuberance (Fig. 269). The skin, dense fasciæ, the posterior borders of the sterno-mastoid and the splenius capitis, are divided, and the margins of the wound well retracted. The artery will then be exposed, lying in a groove on the internal aspect of the base of the mastoid process. It is separated from adjacent veins, and the needle passed from either side. Care must be taken not to divide the artery as it lies upon the bone.

FIG. 269.—Ligature of occipital artery. *a.* Position of external incision.

The middle meningeal artery.—The middle meningeal artery is a branch of the internal maxillary, given off in the pterygoid region, and passing into the skull through the foramen spinosum. It lies in a groove in the temporal bone, and is partially embedded in the outer layers of the dura mater. The artery divides into anterior and posterior branches, to either of which a ligature may have to be applied. The anterior branch passes upwards and slightly backwards, and the posterior backwards and upwards, towards the region of the parietal eminence.

Ligature of the anterior branch of the middle meningeal.—*Position.*—The patient is placed in the dorsal position, with the head raised and turned towards the opposite side. The surgeon stands at the affected side of the head, and the assistant immediately opposite to him.

Special instruments.—In addition to the ordinary instruments for the ligature of a blood vessel, those for trephining are also required.

Operation.—The pterion serves for the centre of the field of operation. A point is taken $1\frac{1}{2}$ in. behind the external angular process of the orbit, and the same distance above the zygoma

(Fig. 271). A flap of the scalp in the form of a semicircle, with a radius of a little more than $1\frac{1}{2}$ in., is reflected, the incision being made with the convexity towards the vertex of the skull, in order to preserve as far as possible the blood supply of the incised tissues. The scalpel divides everything down to the surface of the bone, including the pericranium, and the flap is reflected with the aid of a periosteal elevator. The middle of the flap turned down should be made to correspond to the position of the artery. When the bone has been exposed, a trephine with a diameter of $1\frac{1}{2}$ in. is applied to the skull, the pin of the instrument being placed over the position of the artery.

FIG. 270.—Ligature of middle meningeal artery. Position of trephine openings in exposure of anterior and posterior branches.—After KRÖNLEIN.

A circle of bone is then removed, care being taken in using the trephine to avoid injury to the dura mater or to the vessel itself. In those cases in which the vessel lies in a canal or a very deep groove in the bone, it is not always possible in the dead subject to avoid injury to the artery; but in the living person, when the operation is done for rupture of the artery, the vessel is usually separated slightly from the bone, and lies out of the way of injury, though this will not be the case if it occupies a canal in the bone. When the middle meningeal artery has been exposed in this manner, it will be seen to lie upon the external surface of the dura mater, and to be accompanied by two small *venæ comites*. The artery is separated from the dura mater, and

the aneurysm needle passed underneath, and the vessel ligated together with its venæ comites. When the artery lies in a canal in the bone, it may be requisite to plug the open mouth of the bony canal with a small piece of wood, or a portion of surgical wax, in order to arrest hæmorrhage.

The main trunk of the middle meningeal artery within the cranium.—This vessel may be ligatured through a trephine aperture, placed a little nearer the zygoma than the above. In applying a ligature to the main artery, it will usually be found necessary to push inwards the dura mater for a short distance below the trephine aperture, in order to freely expose the vessel.

FIG. 271.

- a.* Ligature of middle meningeal artery (main branch). Shape of flap, and position of application of trephine.
b. Point for application of trephine, in exposure of lateral sinus.

This can in most cases be fairly easily effected with the periosteal elevator.

The posterior branch of the middle meningeal artery.—This vessel may be ligatured in a manner similar to the above, the trephine aperture being made about $1\frac{1}{2}$ in. above the base of the mastoid process, and just below and in front of the parietal eminence (Fig. 270).

The internal carotid artery.—This vessel is one of the terminal branches of the common carotid artery, and is given off at the level of the upper border of the thyroid cartilage. From this point the artery passes upwards to the base of the skull, where it enters the carotid canal in the petrous bone. At its commencement the internal carotid lies a little external and in a plane somewhat posterior to that of the external carotid. As

it passes upwards it takes a course behind the digastric, and is very deeply placed. A ligature is only applied to this artery immediately above its commencement.

Operation.—The skin incision and early stages of the operation are similar to those described for the external carotid (Fig. 265), and when this vessel has been exposed it is retracted to the inner side. The sheath of the internal carotid is thus laid bare, and is opened in the usual manner. The needle is passed from the outer side so as to avoid injury to the internal jugular vein. Care must be taken not to include the vagus or the cervical sympathetic trunk, which lies immediately posterior to the artery at this point.

Collateral circulation.—This is established through the communications of the two internal carotids in the circle of Willis within the cranium.

The subclavian artery.—The subclavian artery on the right side arises from the innominate artery behind the sterno-clavicular articulation, and on the left side from the arch of the aorta opposite a point immediately to the left of the centre of the manubrium sterni. The artery on each side terminates at the outer border of the first rib, where it becomes axillary. The course of the vessel is divided into three parts, the first portion being that section which lies internal to the scalenus anticus, the second that which lies behind this muscle, while the third or terminal part extends from the outer border of the scalenus anticus to the outer margin of the first rib. The first and second parts of the vessel are very deeply placed, and almost inaccessible for the application of a ligature. The first part of the artery has been ligatured through an incision similar to that which has been described in the case of the innominate artery.

When the arm lies against the side, the course of the subclavian artery is marked out by drawing a line from the centre of the sterno-clavicular articulation to the central point of the clavicle in such a manner that it describes a curve, the centre of whose convexity is situated about three-quarters of an inch above the clavicle. The thoracic portion of the left subclavian is represented by a line from a point a little to the left of the centre of the manubrium sterni to the left sterno-clavicular articulation.

The third part of the subclavian artery lies somewhat superficial. It is covered in front by a process of the deep cervical fascia, and often overlapped by the lower margin of the posterior belly of the omo-hyoid muscle; beneath and below which lie the transversalis colli and superior and posterior scapular veins in a

plexiform arrangement; whilst more superficially it has the nerve to the subclavius, the deep fascia, the superficial fascia containing the platysma, the external jugular vein, the supra-clavicular nerves, and the skin. The dome of the pleura lies below and behind the vessel; the upper surface of the first rib below; the scalenus medius posteriorly; and the cords of the brachial plexus above; the cord formed by the last cervical and first dorsal nerve being situated nearest to the artery. The subclavian vein is anterior, and at a lower level than the artery. The position of the external jugular vein is somewhat variable, but it will usually be met with in the early part of the operation, lying anterior to the artery and at a higher level. No branches are normally given off from this part of the subclavian artery, but occasionally the posterior scapular or the supra-scapular artery arises from the third part of the subclavian.

Ligature of the subclavian artery in the third part of its course.—*Position.*—The patient is placed in the dorsal position, the shoulders raised by a hard pillow, the head turned towards the opposite side, and the arm on the side of the operation drawn well down. The surgeon stands opposite the shoulder on the affected side, and the chief assistant immediately opposite to him.

Operation.—With the left hand the skin is drawn downwards over the middle of the clavicle, and an incision 3 in. in length made, extending to the bone, and dividing the skin, platysma, superficial fascia, and the descending cervical nerves which lie in it. The skin is allowed to retract upwards, and then the deep fascia is incised for the full extent of the incision. In this part of the operation the external jugular vein may be met with, in which case it is pulled upwards out of the field of operation; or, if this cannot be easily effected, two ligatures are passed around it a short distance apart, and tied, and the vein divided between them. Great care must be taken not to wound the vein before ligatures are applied, since its wall is closely united to the margins of the aperture by which it passes through the deep fascia; and if it be wounded, air is liable to be drawn inwards, owing to negative pressure which normally exists in the blood stream in this vessel. If the patient is muscular, the posterior border of the sterno-mastoid and the anterior border of the trapezius will be exposed, and it will be requisite to divide them at the extremities of the incision. When the deep fascia has been fully divided, the posterior belly of the omo-hyoid is sought for immediately above the clavicle, and its inferior margin defined, and then the entire structure is drawn upwards. The

position of this muscle varies according to the degree to which the arm is drawn downwards. When the omo-hyoid has been distinguished, its lower border is traced inwards, and the fascia which lies behind it incised, the small nerve which passes downwards to the subclavius muscle being generally cut at the same time. The plexus of veins in this neighbourhood must then be carefully divided or drawn aside. When this has been done, the outer border of the scalenus anticus is sought for in the inner part of the wound, and when found it is traced downwards until its insertion into the scalene tubercle on the upper aspect of the first rib can be felt. When this tubercle has been defined, the fascia immediately above and behind it is carefully divided, when the subclavian artery will be exposed in the third part of its course, lying in a groove on the rib. The sheath of the

FIG. 272.—Ligature of subclavian artery. Position of patient, and line of skin incision.

vessel is opened in the usual manner and separated for a short distance, and the aneurysm needle passed from the nerves which lie above the artery. Care must be taken not to pierce the vein with the needle. The brachial plexus lies at a higher level in the neck, but if the above stages are not carried out, it occasionally happens that a cord of the plexus is tied instead of the artery, or is included within the ligature which surrounds the vessel. On the dead subject this mistake is frequently made, owing to the absence of pulsation; whilst the vein may be tied, or even a ligature passed around the posterior belly of the omo-hyoid muscle, or a lymphatic gland.

Collateral circulation.—This is very free owing to the numerous channels of communication, and is effected by the following vessels:—(a) The superior thoracic artery, with the

superior intercostal and intercostal branches of the internal mammary in the first intercostal space. (b) The pectoral branches of the acromio-thoracic and the long thoracic, with the intercostal branches of the internal mammary and the thoracic aorta in the upper four or five intercostal spaces. (c) The sub-scapular artery, with the intercostal branches of the thoracic aorta in the second to the sixth spaces, and by means of its dorsalis scapulæ branch with the supra-scapular and posterior scapular branches of the subclavian. (d) Acromial branches of the acromio-thoracic artery, with similar branches from the transverse cervical branch of the thyroid axis.

The inferior thyroid artery.—This artery is one of the branches of the thyroid axis, and supplies the lower portion of the lateral lobe of the thyroid gland. It passes behind the common carotid sheath, about the level of the sixth cervical vertebra. It gives off the ascending cervical artery, and a ligature is usually applied distal to the origin of this vessel.

Position.—The positions of the patient, surgeon, and assistant are the same as for ligature of the common carotid in the lower part of its course.

Operation.—The incision and the different stages of the operation are similar to those for ligature of the common carotid below the omo-hyoid. When the carotid sheath has been exposed, the fascia on its inner side is divided, and the entire sheath with its contents retracted to the outer side. In the interval on the inner side of the sheath, the carotid tubercle of the sixth cervical vertebra is sought for; and, immediately below this, the inferior thyroid artery will be found running inwards from behind the sheath. The vessel is carefully separated from the surrounding structures, and the ligature applied, the needle being passed from below.

The vertebral artery.—The vertebral artery is a branch of the first part of the subclavian artery, and from its point of origin passes upwards to enter the costo-transverse foramen of the sixth cervical vertebra, immediately behind the carotid tubercle.

Operation.—The operation for its ligature is similar to that for the common carotid below the omo-hyoid muscle, or for the inferior thyroid artery. When the carotid tubercle has been defined, the margins of the wound are well retracted, and at the same time the inferior thyroid artery is hooked downwards. In the space immediately below and posterior to the carotid tubercle, the vertebral artery will be discovered, by careful dissection, lying surrounded by its venæ comites. When the artery has

been exposed, the vein, if possible, is drawn to the outer side, and the aneurysm needle is passed from without inwards, care being taken not to include any of the branches of the cervical sympathetic which lie in close proximity.

Collateral circulation.—This is established through the various communications of the two sides in the circle of Willis.

The internal mammary artery.—The internal mammary artery is a large branch given off from the first part of the subclavian. It passes downwards, lying first behind the sternoclavicular articulation, and then behind the costal cartilages and intercostal spaces, about half an inch outside the lateral margin

of the sternum. Opposite the lower border of the sixth costal cartilage it terminates by dividing into the superior epigastric and the musculophrenic arteries.

The course of the vessel is indicated by drawing a line from the central point of the sternoclavicular joint downwards to the sixth costal cartilage, or the sixth interspace, about half an inch from the margin of the sternum.

FIG. 273. — Ligature of internal mammary artery. Position of skin incision.

The internal mammary artery lies upon a thin layer of fascia, which separates it from the parietal pleura in the upper part of the thorax, and lower down upon the triangularis sterni muscle.

Position.—The patient is placed in the dorsal position, the surgeon stands on the affected side, and the assistant on the opposite side.

Operation.—An incision about $1\frac{1}{2}$ in. long, is made across the middle of one of the intercostal spaces, preferably the second or third, commencing a short distance from the middle line of the sternum, and extending outwards at right angles to the course of the artery (Fig. 273). This incision divides the skin, superficial fascia, deep fascia, sternal fibres of the pectoralis major muscle, anterior intercostal membrane, and lastly the internal intercostal muscle, when the artery will be exposed lying upon

the pleura and having a vein usually on each side. The needle is passed from the outer side. In making the incision, great care must be exercised to avoid puncturing the pleura, and notching the underlying lung, or dividing the vessel itself transversely, as it lies on the pleura. It is much more difficult to apply a ligature to the vessel in the lower intercostal spaces, on account of the small distance between the adjacent costal cartilages.

Collateral circulation.—This is established through the anastomoses of the intercostal branches of the internal mammary with similar branches from the superior intercostal or from the thoracic aorta, and through the communication of the superior epigastric artery with the deep epigastric in the region of the umbilicus.

The axillary artery.—The axillary artery is the continuation of the subclavian. It commences at the outer border of the first rib, and terminates at the lower border of the teres major, where this muscle forms the posterior fold of the axilla.

At its commencement the artery lies behind the central part of the clavicle and the subclavius muscle, then behind the costo-coracoid membrane, which separates it from the clavicular portion of the pectoralis major, next behind the pectoralis minor, then behind that part of the pectoralis major which forms the anterior fold of the axilla, and finally behind the deep fascia of the arm as it becomes continuous with the pectoral fascia. That portion of the artery which extends between the outer border of the first rib and the upper border of the pectoralis minor is called the first part, and measures usually a little more than an inch in length; the second part lies behind the pectoralis minor, and measures a little less than an inch; whilst the third part comprises the remainder of the vessel, and extends from the lower border of the pectoralis minor to the lower margin of the teres major, measuring a little more than 3 in. in length. The first part of the artery lies upon the upper two serrations of the serratus magnus muscle, as they cover the first intercostal space and the second rib, and also behind it are the posterior thoracic nerve and the connective tissue which lies between the serratus magnus and subscapularis; the second portion lies upon the posterior cord of the brachial plexus, and the subscapularis; whilst the third part has the musculo-spiral and circumflex nerves behind it, and also the lower part of the subscapularis, and the latissimus dorsi and teres major tendons. The axillary vein lies on the inner side of the vessel and on a slightly anterior plane for its entire course, but separated by nerve cords in the lower part. On the outer side, and above the first

portion, there is the brachial plexus; the second part of the artery is surrounded by the cords of the plexus; and in the third part of its course the branches of the plexus lie around it. The third part of the artery is often crossed by the external vena comes of the brachial artery, as it passes inwards to join the internal vena comes, and so form the commencement of the axillary vein.

The course of the axillary artery is marked out by placing the limb at right angles to the trunk with the forearm supinated, and drawing a line from the central point of the clavicle to the central point of the antecubital fossa. This line marks out both brachial and axillary arteries, the axillary extending from the clavicle to the lower margin of the posterior fold of the axilla.

The axillary artery may be ligatured in the first or third part of its course, the former operation being the more difficult, and very rarely performed except on the dead body.

Ligature of the first part of the axillary artery.—*Position.*

—Place the patient upon the back near the edge of the table, with a flat pillow underneath the scapular region of the affected side, so as to press inwards the scapula towards the spine; the arm lies by the

FIG. 274.—Ligature of axillary artery (first part). *a.* Position of skin incision.

side, but the point of the shoulder is not depressed. The surgeon stands at the outer side of the upper part of the limb when operating on the left side, and opposite the tip of the shoulder when the artery on the right side is to be dealt with. The chief assistant stands directly opposite the operator.

Operation.—An incision about $\frac{1}{4}$ in. long is made, commencing immediately below and two-thirds of an inch outside the sterno-clavicular articulation, and extending to the inner side of the apex of the coracoid process (Fig. 274). The skin, superficial fascia containing platysma and supra-clavicular nerves, the deep fascia covering the pectoral muscle, and the clavicular portion of the pectoralis major, are divided in the line of the incision, care being taken to avoid the cephalic vein as it lies in the outer portion of the wound. The pectoralis major may either

be detached from the clavicle or its fibres cut through. The margins of the wound are retracted and the costo-coracoid membrane sought for, the subclavius being defined above and the pectoralis minor below. The costo-coracoid membrane is next incised, and the cephalic vein and other structures which pierce it pulled aside, together with the exposed muscles (subclavius and pectoralis minor). The pectoralis minor is retracted outwards. The first part of the axillary artery will then be visible, with the vein lying to the inner side and somewhat overlapping it. The sheath is opened in the usual manner, and the needle passed from below so as to avoid damage to the vein. The brachial plexus lies at a higher level, but in the dead body it is possible to apply a ligature to one of the cords instead of the artery. The ligature may be applied to the vessel above or below the origin of the superior thoracic and acromio-thoracic arteries. In the former case, the *collateral circulation* will be the same as after ligature of the third part of the subclavian, and in the latter the humeral branch of the acromio-thoracic will form a communication with the anterior circumflex, and the pectoral branches with similar branches from the long thoracic.

Ligature of the third part of the axillary artery.—

Position.—The patient is placed in the dorsal position, with the affected limb at right angles to the trunk, and supinated. The surgeon stands between the limb and the trunk opposite the axilla, and the chief assistant on the outer side of the upper arm opposite the operator.

Operation.—An incision 3 in. long is made in the line of the artery, commencing above at a point a third of the distance from the anterior to the posterior fold of the axilla (Fig. 275, *a*). This incision divides the skin, superficial fascia, and deep fascia, and when the margins of the wound are retracted the artery is exposed. The external vena comes off the brachial artery often crosses it, whilst the median nerve, or its inner head, lies in front of it, and the coraco-brachialis overlaps it from the outer side. The median and musculo-cutaneous nerves, together with the coraco-brachialis muscle, are drawn to the outer side, the artery is separated from the adjacent veins—which in the lower part of the axilla may be numerous—and the aneurysm needle passed from the inner side, care being taken not to include the ulnar and internal cutaneous nerves which lie on the inner side, or the musculo-spiral nerve which lies behind.

Collateral circulation.—The channels by which the collateral

circulation is established, after ligature of the third portion of the axillary, vary according to the position of the ligature.

When the ligature is applied above the origin of the subscapular artery, they are—(a) The posterior circumflex with acromial branches of the acromio-thoracic and the supra-scapular; (b) the subscapular, by means of its dorsal scapular branch, with the supra-scapular and the posterior scapular, and by its thoracic branches with similar branches from the intercostal arteries of the upper four to six spaces and also from the long thoracic.

When the ligature is applied between the subscapular and the circumflex arteries, the chief channels are the communications between the posterior circumflex and the acromial branches of the acromio-thoracic and supra-scapular arteries.

FIG. 275.—Ligature of arteries of upper extremity.

|--|--|
| a. Incision for third part of the axillary artery. | c. Incision for brachial at bend of elbow. |
| b. Incision for brachial at middle of arm. | d. Incision for radial at middle of forearm. |
| e. Incision for radial at wrist. | |

If the ligature is below the circumflex arteries, the channels are similar to those after ligature of the brachial above the superior profunda, namely, communications between ascending branches of the superior profunda and branches of the circumflex arteries, chiefly the posterior.

The brachial artery.—This vessel commences at the lower border of the *teres major*, and terminates in the ante-cubital fossa, anterior and slightly to the ulnar side of the neck or head of the radius, by dividing into the ulnar and radial arteries.

Its course has been marked out along with that of the axillary artery.

The artery lies upon the musculo-spiral nerve and superior profunda artery, then upon the internal head of the triceps, the insertion of the *coraco-brachialis*, the *brachialis anticus*,

and at its termination upon the tendon of the biceps. For the greater part of its extent it is superficial, but at the elbow it lies underneath the bicipital fascia and between the supinator longus and pronator radii teres muscles. It is overlapped, especially in muscular subjects, by the biceps, and it is crossed from without inwards (usually about the middle of the arm) by the median nerve. The vessel has two venæ comites, one on each

side, these structures often being connected by large cross branches.

The artery may be ligatured in the middle of the upper arm, or at the bend of the elbow.

Ligature of the brachial artery at the middle of the upper arm.—*Position.*—The patient is placed on his back near the edge of the table; the arm is abducted to a right angle, and

held in the supine position. An assistant should stand on the outer side of the limb and support it at the elbow, or allow the elbow, but not the upper arm, to rest on a small table, otherwise the triceps may affect the position of the biceps and so obscure the vessel. The operator stands between the limb and the trunk, and a second assistant opposite him.

Operation.—An incision $2\frac{1}{2}$ in. long is made in the line of the vessel, its central point corresponding to the middle of the upper arm (Fig. 275, *b*). The skin, superficial fascia containing the basilic vein, and the deep fascia are divided, and the inner border of the biceps muscle exposed. Care must be exercised not to mistake the triceps for the biceps, and to avoid injury to the basilic vein. The biceps is retracted outwards, when the artery will be exposed lying upon the triceps, surrounded by its *venæ comites*, and with the median nerve usually in front. The median nerve is drawn to whichever side is most convenient, the artery separated from its *venæ comites*, and the needle passed from the nerve. In the dead subject the basilic vein is occasionally ligatured instead of the artery, but this mistake can be easily prevented by taking care that the deep fascia is divided and the biceps exposed.

Collateral circulation.—If the ligature is applied above the origin of the superior profunda, the collateral circulation is established by communications between ascending branches of the superior profunda with branches of the circumflex arteries, especially the posterior. When it is ligatured between the superior and inferior profunda vessels, the principal communications are between the *anastomotica magna*, the radial recurrent, and the interosseous recurrent, with the terminal branches of the superior profunda.

If below the origin of both profunda arteries, in addition to the above, the *anastomotica magna*, and the anterior and posterior ulnar recurrent with the inferior profunda.

Ligature of the brachial artery at the bend of the elbow.

—*Position.*—Similar to that for ligature of the artery in the middle of the arm, except that the limb may rest on the table.

Operation.—An incision about 2 in. long is made, commencing on the right side immediately above and internal to the central point of the bend of the elbow, and extending upwards and inwards, parallel with the inner border of the biceps muscle (Fig. 275, *c*). The skin, superficial fascia containing the superficial veins and nerves, and the deep fascia, which is strengthened by the bicipital fascia, are divided, the veins and nerves being retracted as they become visible. The vessel is now exposed,

surrounded by its venæ comites, and with the median nerve on its inner side and the biceps on the outer side. The vessel is separated from its veins, and the needle passed from the inner side.

Collateral circulation.—This is established along the channels

which have been enumerated, after ligature of the brachial below both profunda arteries.

The ulnar artery.—The ulnar artery is one of the terminal branches of the brachial; it commences in the antecubital fossa, and terminates beyond the pisiform bone by dividing into superficial and deep branches.

In its course downwards it lies upon the insertion of the

brachialis anticus, then upon the flexor profundus digitorum, and finally on the anterior annular ligament of the wrist. In the upper part of its course it lies behind some of the flexor group of muscles which come from the internal condyle; in the next part it is overlapped by the flexor carpi ulnaris, and in the region of the wrist it is covered by fascia and skin only. The ulnar nerve lies on its ulnar side for the lower half of the forearm. The course of the artery is represented in the lower two-thirds of the forearm, by drawing a line from the apex of the internal condyle of the humerus to the radial side of the pisiform bone, and in the upper third by continuing the course of the vessel upwards to the central point of the antecubital fossa.

The artery may be ligatured in the upper middle or lower third; in the upper third it is very deeply placed.

Ligature of the ulnar artery in the upper third.—*Position.*—The arm is placed at right angles to the body on a small table and held in the supine position. The surgeon stands on the inner or outer side of the arm, and the assistant opposite to him.

Operation.—A point is taken midway between the condyles of the humerus, and an incision made downwards from this in the line of the artery. The skin, superficial fascia containing branches of the internal cutaneous nerve, the median basilic and anterior ulnar veins are divided, the latter structures being drawn aside. The deep fascia, thickened in this situation to form the bicipital fascia, is then divided in the line of the incision, and the radial border of the pronator radii teres defined. This structure is drawn to the ulnar side together with the median nerve which lies immediately beneath it, and the artery sought as it passes under the muscle.

It is carefully separated from the surrounding veins, and the needle passed from the radial side.

Ligature of the ulnar artery in the middle third of the forearm.—*Position.*—As for ligature at the bend of the elbow.

Operation.—An incision from $2\frac{1}{2}$ to 3 in. long is made in the line of the vessel, the central point corresponding to the middle of the forearm (Fig. 278, a). The skin, superficial fascia containing the anterior ulnar vein and branches of the internal cutaneous nerve, and the deep fascia, are divided, the muscles are exposed, and the interval between the flexor carpi ulnaris and the flexor sublimis digitorum sought for with the finger. When this has been found, the muscles are separated, and the artery will be seen lying upon the flexor profundus digitorum, surrounded by

its venæ comites, and with the ulnar nerve on its inner side. The vessel is now separated from its accompanying veins, and the needle passed from the ulnar side.

Ligature of the ulnar artery in the lower third of the forearm.—*Position.*—As for ligature in the middle third.

Operation.—An incision about 2 in. long is made in the line of the vessel, commencing about 1 in. above the pisiform bone and extending upwards (Fig. 278, *b*). The skin, superficial fascia, and deep fascia are divided, and the artery sought for in the interval between the flexor carpi ulnaris and flexor sublimis digitorum muscles. The artery, when exposed, is separated from the ulnar nerve, which lies on the ulnar side, and also, if possible, from the venæ comites, and then the needle is passed from the ulnar side.

Collateral circulation.—This is very easily established through the free communications of the palmar arches, and also through the anterior and posterior interosseous arteries and the carpal arches.

The radial artery.—The radial artery commences at the bifurcation of the brachial at the bend of the elbow, and terminates on the dorsal aspect of the wrist, where it passes between the two heads of the first dorsal interosseous muscle to enter into the formation of the deep palmar arch.

Its course is represented by a line drawn from the central point of the antecubital fossa to a point about half-way between the tuberosity of the scaphoid and the styloid process of the radius, whence it winds round the lateral aspect of the wrist across the “tabatière” to the base of the first inter-metacarpal space.

It lies upon the tendon of the biceps, the supinator brevis, the pronator radii teres, the radial head of the flexor sublimis digitorum, the flexor longus pollicis, the pronator quadratus, the anterior aspect of the lower end of the radius, the anterior and lateral ligaments of the wrist joint, and finally on the dorsal surface of the trapezium. In the first part of its extent it is covered by the supinator longus, then it lies superficially, and lastly it passes beneath the extensor muscles of the thumb. It is accompanied by two venæ comites, but the radial nerve lies in contact with the vessel on the radial side for the middle third only of its course.

FIG. 278.—Ligature of ulnar artery.
Position of skin incisions.

- a.* In middle third of forearm.
- b.* In lower third of forearm.

The radial artery may have a ligature applied to it in the upper, middle, and lower thirds of the forearm, and also as it lies in the "tabatière" on the dorsal aspect of the wrist.

Ligature of the radial artery in the upper third.—*Position.*—As for the ulnar artery.

Operation.—An incision a little over 2 in. in length is made in the upper third of the forearm, in the line of the vessel. The skin, superficial and deep fasciæ, are divided, and the interval between the supinator longus and the pronator radii teres sought for. The fibres of the former muscle run in a vertical direction, and those of the latter obliquely downwards and outwards. When this interval has been defined, the muscles are separated and the artery exposed. The needle may be passed from either side, the vessel being separated from its venæ comites if possible.

Ligature of the radial artery in the middle third.—*Position.*—As in the preceding operation.

Operation.—An incision from 2 to 3 in. long is made in the middle third of the forearm over the line of the artery (Fig. 275, *d*). The skin, the superficial fascia containing the radial vein and branches of the musculo-cutaneous nerve, and the deep fascia are divided, care being taken not to injure the superficial veins or nerves. The ulnar border of the supinator longus, which in this position is muscular above and tendinous below, is defined, and the muscle retracted towards the radial side. The radial vein lies on the outer side, but some distance away from the vessel. The artery is then exposed, lying upon the insertion of the pronator radii teres and surrounded by its venæ comites. These latter structures are separated from the vessel, and the needle passed from whichever side is found to be the more convenient.

Ligature of the radial artery in the lower third.—*Position.*—As for ligature of the vessel in the middle third.

Operation.—An incision about $1\frac{1}{2}$ in. in length is made, commencing a little above the level of the tuberosity of the scaphoid, and extending upwards in the line of the artery (Fig. 275, *e*). The skin and fascia are divided, and the interval between the ulnar border of the supinator longus and radial margin of the flexor carpi radialis opened up, care being taken not to injure the superficial veins or to divide the artery longitudinally as it lies in the bottom of the wound. The venæ comites are separated, and the needle passed from either side. In many cases it will be found necessary to include the veins in the ligature.

Ligature of the radial artery on the dorsum of the wrist.

—*Position*.—The hand is placed in a position half-way between supination and pronation, resting on its ulnar border, and held by an assistant. The surgeon stands on the outer side of the limb, and the assistant opposite to him.

Operation.—An incision about 1 in. in length is made, commencing immediately below the styloid process of the radius, and running across the “tabatière” half-way between the tendon of the extensor primi internodii pollicis and that of the extensor secundi internodii pollicis. The skin and fasciæ are divided, the margins of the incision retracted, and then the artery will be exposed, lying upon the dorsal aspect and radial side of the wrist. The needle is passed from either side. Care must be taken, in the performance of this operation, to avoid injury to the adjacent tendon sheaths or the underlying joints.

Collateral circulation.—The collateral circulation, after liga-

FIG. 279.—Ligature of radial artery on dorsum of wrist.
Position of hand and line of skin incision.

ture of the radial artery, is established in a manner similar to that which occurs when the ulnar artery is occluded.

Ligature of an intercostal artery.—In each intercostal space intercostal arteries are found, one above and one below, the former being the larger. Each vessel lies in a groove in the rib which forms a boundary of the intercostal space (Fig. 339). It is occasionally necessary to apply a ligature to the vessel as it lies in this groove.

Position.—The patient is so placed that the area of the operation is well exposed.

Operation.—An incision about 2 in. in length is made over the rib, and in the direction of the blood vessel which it is proposed to ligature. The surface of the rib is exposed, the periosteum separated, and a portion of the rib overlying the vessel removed subperiosteally. When this has been done, the artery is laid bare, and a ligature can easily be applied. In cases of injury it will usually be found requisite to place a ligature on each extremity of the artery as it lies exposed in the bottom of

the wound, on account of the free anastomoses between the vessels in each intercostal space.

Abdominal aorta.—The abdominal aorta lies upon the anterior aspect of the posterior abdominal wall, its point of bifurcation being upon the left side of the lower portion of the body of the fourth lumbar vertebra.

This is marked out on the surface of the abdomen by taking a point half an inch to the left of the middle of a line drawn between the highest points of the two iliac crests, or by taking a point which is three-quarters of an inch below and half an inch to the left of the umbilicus. The vessel extends upwards from this point in an almost vertical direction, reaching the middle line of the abdomen above.

The inferior vena cava lies to the right of the aorta, and tends to overlap it, whilst it is surrounded by the aortic plexus of the sympathetic, and has lying in front of it, just above its bifurcation, the inferior mesenteric artery, the parietal peritoneum, and the small intestines.

The vessel has only been ligatured a few times; all the cases have been fatal, usually within a few hours, but one case lived for ten days.

Position.—The patient is placed in the dorsal position; the surgeon stands upon the right side and the chief assistant upon the left.

FIG. 280.—Ligature of abdominal aorta. *a*. Position of parietal incision.

Operation.—An incision 3 or 4 in. in length is made half an inch to one or other side of the linea alba, one-third of the incision being below the point of bifurcation, and two-thirds above. The peritoneum is opened for the entire length of the incision, the small intestines and great omentum are pushed upwards and to the right, and held there by the hands of an assistant or by large flat sponges, and in this way the anterior aspect of the lower portion of the vessel is exposed, except that it is covered with peritoneum. This peritoneum is divided by a vertical incision, and lifted away from the vessel by the finger. The inferior mesenteric artery is then defined and pushed over to the left, and a point half-way between the origin of this vessel and the bifurcation of the aorta is selected for the appli-

cation of the ligature. The vessel is then separated from the connective tissue and the plexus of sympathetic nerves which surrounds it, and a large curved aneurysm needle passed from the right side. This is threaded with a thick silk ligature, and withdrawn. The ligature is then tied, the ends cut short, and the peritoneum replaced, and united with interrupted silk suture. All sponges are then removed, and the external wound closed.

The above is the *intra-peritoneal* method of operation. An *extra-peritoneal* operation has been performed, but this was made use of chiefly in the pre-aseptic days.

The common iliac artery.—A line drawn from the point of bifurcation of the abdominal aorta to the central point of a line from the anterior superior iliac spine to the symphysis pubis, represents the course of the common and external iliac arteries, the upper third corresponding to the common iliac, and the lower two-thirds to the external iliac vessel.

The common iliac artery extends from the lower part of the fourth lumbar vertebra to a point opposite the lumbo-sacral articulation. It is covered in front by peritoneum, branches of the sympathetic passing to the hypogastric plexus, and at its point of division it is crossed by the ureter. The right common iliac artery is in relation with the commencement of the inferior vena cava and both common iliac veins. Each common iliac vein lies posterior and internal to the corresponding artery at first, but the left vein crosses behind the upper portion of the artery of the right side, and there joins the right vein, which has already passed behind, so as to form the inferior vena cava. The operation of ligature of the common iliac artery may be carried out through the peritoneum, when the procedure is known as *intra-peritoneal*, or it may be performed *extra-peritoneally* through either an anterior or a lateral incision.

The *intra-peritoneal* operation is the more preferable one, owing to the ease with which the vessel can be exposed, and the lessened dangers of injury to adjacent viscera.

Intra-peritoneal operation.—*Position.*—The patient is placed in the dorsal position, with the side which is to be operated upon slightly raised. The surgeon stands on the same side of the patient as the artery, and the chief assistant on the opposite side.

Operation.—An incision about 4 in. long is made half an inch to one or other side of the linea alba or the linea semilunaris, commencing below at a point one-third of the distance from the symphysis pubis to the umbilicus, and extending upwards beyond the umbilicus (Fig. 281, *b*). The peritoneal

cavity is opened, the intestines and great omentum pushed upwards and towards the sound side, and kept out of the field of operation by flat sponges or the hands of an assistant, and the position of the vessel defined as it lies behind the peritoneum a short distance below the point of bifurcation of the aorta. The peritoneum over the artery is divided for about 1 in. in front of the middle portion, care being taken not to injure the ureter or the branches of the sympathetic. With a long, curved aneurysm needle the artery is separated from its sheath for nearly half an inch, and then the needle is passed from the inner side, threaded, and withdrawn. The ligature is then tied, and the ends cut short. If a long incision has been made through the peritoneum in front of the artery, the margins may

be approximated with one or two points of interrupted suture, but usually this is unnecessary. All sponges are removed, and the parietal wound closed in the usual manner.

Extra-peritoneal operation.—(a)

By ANTERIOR INCISION.—*Position.*—As for the preceding.

Operation.—An incision from 5 to 8 in. long is made, commencing $1\frac{1}{2}$ in. above and immediately to the outer side of the central point of Poupart's ligament, and curving upwards and outwards, first to within $1\frac{1}{2}$ in. of the anterior superior spine of the ilium, then more vertically upwards towards the costal margin, and finally inwards

FIG. 281.—Ligature of common iliac artery.

- a. Incision for extra-peritoneal operation on right side.
- b. Incision for intra-peritoneal operation on left side.

in the direction of the umbilicus (Fig. 281, a). The various strata of the abdominal wall are divided until the layer of extra-peritoneal fatty tissue is recognised, when the peritoneal sac is separated by the fingers from the iliac fascia until the external iliac artery is seen. The latter is traced upwards until the common iliac artery is reached, the ureter and the sympathetic nerves are pushed aside, and the common iliac artery cleared. The ligature is passed in a manner similar to that described in the intra-peritoneal operation. When the ligature has been applied, the parietal wound is closed by the insertion of two or three tiers of sutures which accurately approximate the different muscular strata and the skin.

(b) **By LATERAL INCISION.**—*Position.*—The patient is placed well upon the sound side. The surgeon and assistant stand as in the operation through an anterior incision.

Operation.—A somewhat curved incision, with the cavity towards the umbilicus, is made, commencing above at the tip of the twelfth rib and extending obliquely downwards to just above the iliac crest, and then forwards until a point immediately above the anterior superior spine of the ilium is reached. This incision is deepened until the fascia transversalis has been divided and the extra-peritoneal tissue exposed. With the fingers the peritoneal sac is separated from the iliac and psoas fasciæ and lifted forwards, when the common iliac artery is seen exposed in the bottom of the wound. The vessel is then separated from the ureter and the common iliac vein, and a ligature passed, the needle being entered on the inner side of the artery. The ligature is then tied, the ends cut short, the peritoneal sac allowed to fall back into its normal position, and the external wound closed.

Collateral circulation.—(a) Superior epigastric artery and branches from the lower intercostal vessels, with the deep epigastric, a branch of the external iliac. (b) The lower lumbar arteries, branches of the abdominal aorta, with the ilio-lumbar, a branch of the internal iliac, and the deep circumflex iliac, a branch of the external iliac. (c) The middle sacral artery, a branch of the abdominal aorta, with the lateral sacral branches of the internal iliac. (d) The terminal branches of the inferior mesenteric, with rectal branches of the internal iliac. (e) Pubic branches of the obturator, with similar branches from the opposite side. (f) In the female, branches of the internal pudic artery, with similar branches from the opposite side, chiefly in the perineum. (g) Branches of the uterine artery, from the internal iliac, with the ovarian, a branch of the abdominal aorta.

The external iliac artery.—The line of the external iliac artery has already been mentioned in connection with that of the common iliac.

The vessel lies upon the brim of the pelvis to the inner side of the psoas magnus muscle above, but at Poupart's ligament it lies directly in front of this structure, though separated from it by the iliac fascia. The lower coil of the ileum crosses the vessel on the right side, and the sigmoid flexure on the left; whilst on both sides the vessel is covered by peritoneum, and crossed at its lower part in the male by the vas deferens and the spermatic vessels, and in the female by the round ligament of the uterus. A short distance above Poupart's ligament the deep circumflex iliac vein crosses the artery to join the external iliac vein.

Position.—The patient is placed in the dorsal position, with the thigh of the affected side slightly flexed. The operator stands on the same side of the patient as the vessel which is to be ligatured, and the assistant on the opposite side.

Operation.—An incision from $3\frac{1}{2}$ to 4 in. long is made, which commences at a point half an inch above the central point of Poupart's ligament, and extends outwards beyond the anterior superior iliac spine, the main part of the incision being parallel with the ligament, while the last inch is curved slightly upwards. The incision divides the various strata of the anterior abdominal wall until the transversalis fascia is reached. This is carefully picked up with forceps at the inner part of the wound and divided for the entire length of the incision, care being taken

FIG. 282.—Ligature of external iliac artery.

a. Incision for Cooper's operation.
b. Incision for Abernethy's operation.

not to injure the adjacent portion of the peritoneum. The peritoneum is next peeled upwards with the fingers from the fascia which covers the iliacus and the psoas magnus, until the artery is seen lying upon the internal margin of the muscle, care being taken, especially when performing the operation on the dead body, not to lift up the vessel with the peritoneum, and allow it to be retracted to one side by the assistant. When the vessel has been exposed, a point is selected a little more than an inch above Poupart's ligament for the application of the ligature. The sheath, which at this point is thin,

is opened in the usual manner, and the aneurysm needle passed from the inner side, care being taken to avoid the vein. The ligature is tied, the ends cut short, and the parietal wound closed. It is advisable, in closing the external wound, to unite the lower border of the internal oblique muscle to the upper portion of Poupart's ligament.

This operation is a modification of that known as "Cooper's operation." Abernethy employed a more vertical incision, which was also placed at a higher level (Fig. 282).

Collateral circulation.—(*a*) The superior epigastric artery and the abdominal branches of the lower intercostal and the lumbar arteries with the deep epigastric, which is given off from the external iliac artery below the point of ligature; (*b*) the lower lumbar arteries (anterior branches) and the iliac branch of the

ilio-lumbar artery with the deep circumflex iliac artery, a branch of the external iliac; (c) the sciatic artery, with the other arteries which enter into the crucial anastomosis; (d) the deep branches of the gluteal artery with the external circumflex and the deep circumflex iliac in the region of the anterior superior iliac spine; (e) perineal branches of the internal pudic artery with similar branches from the external pudic, a branch of the common femoral; (f) pubic branches of obturator artery with pubic branches of deep epigastric.

The deep epigastric artery.—The deep epigastric artery is a branch of the external iliac given off immediately above Poupart's ligament.

Its course is marked out by taking a line from the central point of Poupart's ligament to immediately outside the umbilicus.

Position.—As for the external iliac artery.

Operation.—An incision 2 in. long, at right angles to the line of the vessel, is made, so that the centre of the incision corresponds to the point where the line of the artery crosses the linea semilunaris (Fig. 283, *a*). The incision is deepened, and the fascial aponeurosis of the external oblique, and the conjoined tendon formed by the union of the internal oblique and the transversalis abdominis, are divided in order, when the fascia transversalis is exposed. The outer border of the rectus abdominis is then drawn inwards with a retractor, and the fascia transversalis divided in the line of the wound. The deep epigastric artery is then exposed lying upon the peritoneum and in the subperitoneal tissue accompanied by two venæ comites. The artery is separated from its accompanying veins, and a ligature passed from the inner side.

The deep circumflex iliac artery.—This vessel is a branch of the external iliac, given off at about the same level as the deep epigastric artery.

Its course is behind and very slightly above the outer half of Poupart's ligament, where it lies upon the iliac fascia, which separates it from the iliacus muscle. At the anterior superior spine of the ilium it pierces the fascia transversalis, and runs between the abdominal muscles close to their attachments to the

FIG. 283.—Position of skin incision in ligature of—

- a.* Deep epigastric artery.
- b.* Deep circumflex iliac artery.

crest of the ilium. The external cutaneous nerve lies behind the vessel.

Position.—As for the external iliac artery.

Operation.—An incision 2 in. long is made parallel with and slightly above the external half of Poupart's ligament (Fig. 283, *b*). This divides the fascial layer, the aponeurosis of the external oblique, the lowest fibres of the internal oblique, the transversalis in the outer two-thirds of the wound, and finally the fascia transversalis, when the vessel is exposed lying upon the iliac fascia, and accompanied in this part of its course by two venæ comites. The needle is passed from either side, care being taken not to include the external cutaneous nerve. A knowledge of the course and relations of the deep circumflex iliac artery is important, as in this region a psoas abscess is often opened.

The femoral artery.—The femoral artery commences opposite Poupart's ligament, where it is continuous with the external iliac, and terminates below at the junction of the middle and lower thirds of the thigh at an aperture in the adductor magnus muscle, where it passes into the popliteal artery.

Its course is marked out by placing the limb in a position of abduction, external rotation, and slight flexion, and then drawing a line from a point midway between the anterior superior iliac spine and the symphysis pubis to the adductor tubercle of the femur. The upper two-thirds of this line represents the course of the vessel, the first $1\frac{1}{2}$ or 2 in. being the common femoral, the part below this in the upper third of the thigh the superficial femoral in Scarpa's triangle, and the remainder the superficial femoral in Hunter's canal. The relations of the vessel in the different parts of its course are shown in Figs. 285 and 287.

About 1 to 2 in. below Poupart's ligament the common femoral artery divides into the superficial femoral and the deep femoral. The parts of the artery to which a ligature may be applied are the common femoral, the superficial femoral in Scarpa's triangle, the superficial femoral in Hunter's canal, and the deep femoral.

Ligature of the common femoral artery.—This vessel lies immediately under the fascia lata, within the femoral sheath, having the ilio-psoas behind, the common femoral vein on the inner side, and the anterior crural nerve and a few fibres of the psoas muscle on the outer side.

Position.—The patient is placed in the dorsal position, with the thigh slightly flexed, abducted, and rotated outwards. The surgeon stands upon the outer side of the limb, and the chief assistant on the opposite side.

Operation.—An incision about 2 in. or $2\frac{1}{2}$ in. in length is made in the line of the artery, commencing above immediately below Poupart's ligament (Fig. 284, *a*). The skin, superficial fascia, and the deep fascia are divided, and the margins of the wound held aside with retractors, when the anterior layer of the femoral sheath will be exposed, the anterior crural nerve lying upon its outer side separated from the artery by a few fibres of the psoas magnus muscle. The crural branch of the genito-crural nerve may be met with, lying upon or within the sheath of the vessel. The artery is situated in the external compartment of the femoral sheath, and lies in close relation with the corresponding vein, which is placed internal to the artery and separated from it by a septum of connective tissue. The sheath is opened somewhat on the outer side, so as to avoid injuring the vein, which may overlap it, and the needle is passed from the inner side. When the ligature has been applied, the wound is closed in the usual manner.

Collateral circulation.—(*a*)

Deep circumflex iliac with the ascending branch of the external circumflex; (*b*) obturator with the internal circumflex; (*c*) sciatic with the other vessels taking part in the crucial anastomosis; (*d*) branches of the internal pudic artery with superficial pudic branches of the common

femoral, when these are given off below the point of application of the ligature. In all cases, where possible, ligature of the external iliac is to be preferred to ligature of the common femoral.

FIG. 284.—Ligature of femoral artery. Position of limb, and lines of external incision.

a. Common femoral.

b. Superficial femoral at apex of Scarpa's triangle.

Ligature of the superficial femoral artery in Scarpa's triangle.—*Position.*—The position of the patient and of the operator is the same as in ligature of the common femoral.

Operation.—An incision 3 to $3\frac{1}{2}$ in. long is made in the line of the artery, and is so placed that the upper two-thirds of the wound are situated in the lower part of the upper third of the thigh, and the lower third of the wound in the upper portion of the middle third of the thigh (Fig. 284, *b*). The vessel is ligatured at the apex of Scarpa's triangle. The superficial fascia is divided, care being taken to avoid injury to tributaries of the long

saphenous vein which may cross the line of the artery in this portion of the thigh; if, however, they cannot be drawn aside, two ligatures are applied, and the vessel divided between them. The deep fascia is then incised, when the sartorius muscle will

be visible, its fibres crossing obliquely from above downwards and inwards. The inner border of the muscle is defined, and the entire muscle drawn outwards, by which means the anterior aspect of the sheath is exposed. The vein lies behind and to the inner side of the artery, whilst the internal cutaneous nerve

lies anteriorly, and the long saphenous nerve externally. The sheath of the artery is opened, and the needle passed from the inner side, care being taken to keep the point of the needle against the wall of the vessel, and so avoid enclosure of any of the adjacent structures. When the ligature has been tied, the ends are cut short, the sartorius allowed to return to its former position, and the external wound closed.

Collateral circulation.—(a) Descending branches of the external circumflex with muscular branches of the superficial femoral, the anastomotica magna, and the superior external articular branches of the popliteal; (b) the perforating branches of the profunda femoris with muscular branches of the superficial femoral, superior muscular branches of the popliteal, and the superior articular branches of the same vessel.

Ligature of the superficial femoral artery in Hunter's canal.—*Position.*

—The same as for ligature of the common femoral, the surgeon standing on the outer side of the middle third of the thigh.

Operation.—An incision from 3 to 4 in. long is made in the line of the artery in the middle third of the thigh, the central point of the incision being opposite the mid-point of the thigh (Fig. 286, *a*). The superficial fascia is divided, and if the internal saphenous vein is seen it is drawn inwards with a retractor. The deep fascia is next incised, and underneath it the sartorius will be exposed, the fibres running from above downwards and inwards. The outer border of this muscle is then defined, and the entire structure drawn inwards, when the aponeurosis which forms the roof of the canal will be exposed. In order to make this more distinct, it may be advisable to abduct the thigh more fully. The aponeurosis is incised in the line of the incision, and the artery with a thin sheath laid bare. In front of the vessel the long saphenous nerve will be visible, on the outer side the nerve

to the vastus internus, and behind the corresponding vein, whilst surrounding the artery are branches of the sympathetic and the deep lymphatic vessels coming up from the popliteal space. The surface of the artery is bared in the usual manner, and the needle passed from either the inner or the outer side, care being

taken not to include a nerve in the ligature, or pierce the vein with the needle.

Collateral circulation.—The circulation is re-established along the same channels as have been enumerated in connection with ligature of the artery in Scarpa's triangle.

The popliteal artery.—The popliteal artery commences at the aperture in the adductor magnus, runs at first slightly outwards, but chiefly downwards, to the middle of the space, when it takes a vertical direction to the lower border of the popliteus muscle, at which point it terminates by dividing into the anterior and posterior tibial arteries.

In its course downwards it lies behind the bare triangular area on the posterior aspect of the lower part of the femur, then upon the posterior ligament of the knee-joint, and finally upon the fascia which covers the popliteus. The vein lies in close relation to the artery, at first being on the outer side and posterior, then posterior, and finally internal. The popliteal nerve is more superficial, but, like the vein, crosses from the outer to the inner side during its course downwards.

FIG. 288.—Transverse section through the right thigh, at the level of the upper part of the popliteal space. The arrow represents the course of the dissection in exposure of the artery. (Seen from below.)

That branch of the obturator nerve which goes to the knee-joint lies upon the upper portion of the artery, between it and the vein.

The popliteal artery may be ligatured in the upper part of its course as it lies behind the femur, or in the lower part where it is in relation with the fascia covering the popliteus.

Ligature of the popliteal artery in the upper part of the popliteal space.—*Position.*—The limb is placed in a position similar to that for ligature of the femoral artery, but is more flexed and rotated outwards.

Operation.—The adductor tubercle is defined, and passing upwards from it can be felt the tendon of the adductor magnus. An incision is made, commencing below half an inch above the adductor tubercle, and extending upwards for $3\frac{1}{2}$ in. along the

posterior border of the tendon (Fig. 286, *b*). The skin, superficial fascia containing branches of the internal cutaneous nerve, and the deep fascia, are divided in the line of the incision; the nerves and the long saphenous vein, if seen, being drawn to one side. The anterior border of the sartorius muscle is then seen, and also the tendon of the adductor magnus. The sartorius is retracted backwards, and the adductor tendon forwards and to the outer side, when the tendon of the semi-membranosus will be exposed. This is drawn inwards and backwards, and on separating the fatty tissue the artery will be found lying close to the bone. It is separated from the vein, which here lies posterior and external to the artery, and the

FIG. 289. — Ligature of popliteal artery in lower part of popliteal space. Position of the skin incision.

needle is passed from the vein, care being taken not to include the geniculate branch of the obturator nerve.

Collateral circulation. — (*a*) The superior external articular arteries, the anastomotica magna, the descending branch of the external circumflex, and the lowest muscular branches of the profunda femoris, communicate with the inferior articular arteries and the recurrent branches of the anterior tibial; (*b*) the articular branches of the anastomotica magna and external circumflex with the azygos branch of the popliteal.

Ligature of the popliteal artery in the lower part of the popliteal space.—*Position.* —The patient is placed in a semiprone position, and the limb fully extended. The surgeon stands on the outer side of the limb which is to be operated upon, and the assistant on the opposite side.

Operation.—An incision is made in the middle line of the popliteal space, 3 to 4 in. in length, commencing immediately below the central point of the space, and extending downwards in the line of the artery (Fig. 289). The skin is divided, and then the superficial fascia, in which will be seen the short saphenous vein and the small sciatic nerve. These structures are retracted to the outer side, and then the deep fascia is divided, when the two heads of the gastrocnemius will be exposed. These are

separated without injuring the large arteries and nerves which go to them, and the short saphenous vein followed till it joins the popliteal vein. The popliteal nerve is generally seen first, then the vein, and, somewhat to the outer side and at a slightly deeper level, the artery. The popliteal nerve and vein are drawn towards the inner side, and the needle passed from these structures. The performance of the deep dissection may be facilitated by flexing the knee slightly, so as to relax the gastrocnemius.

Collateral circulation.—Similar to that which is established after ligation of the first part of the artery.

The posterior tibial artery.—The course of the posterior tibial artery is represented by drawing a line from the central point of the popliteal space to a point half-way between the tip of the internal malleolus and the inner side of the prominence of the heel. The artery commences at a point in the leg on a level with the tubercle of the tibia, and in the first part of its course it lies a little internal to the above line.

FIG. 290.—Position of limb and lines of incision for exposure of the posterior tibial artery in the middle and lower thirds of the leg, and at the ankle behind the internal malleolus.

a. Middle third. | b. Lower third.
c. At ankle.

The upper part of the artery is deeply placed in the calf, lying underneath the soleus and gastrocnemius muscles, and the deep transverse fascia of the leg which separates the superficial group of muscles from the deep (Fig. 291). In the lower third of the leg it is more superficial, and lies immediately below the deep fascia. In its course downwards it lies upon the tibialis posticus, the flexor longus digitorum, the posterior surface of the tibia, and the ligaments of the ankle-joint. The posterior tibial nerve lies on the outer side of the artery, except for a short distance at its commencement. The artery is accompanied by two venae comites.

A ligature may be applied to the posterior tibial artery in the

middle third of the leg, in the lower third of the leg, or at the ankle-joint.

Ligature of the posterior tibial artery in the middle third of the leg.—*Position.*—The patient lies in the dorsal position,

| | 27. Gastrocnemius. |

the limb to be operated upon is flexed at the knee, and the leg lies upon its outer side. The surgeon stands on the outer side of the limb and leans over, the assistant being placed opposite him.

Operation.—The postero-internal border of the tibia is defined,

and an incision 3 to 4 in. long made parallel to this border, but about half an inch behind it, in the middle third of the leg (Fig. 290, *a*). The skin and superficial fascia are divided, and if the internal saphenous nerve and vein are seen, they are retracted to the inner side or backwards. The deep fascia is then incised, and underneath it the soleus, where it is attached to the postero-internal border of the tibia, made out. In this part of the operation, in a muscular subject, the edge of the gastrocnemius may become visible, in which case it is drawn backwards. When the soleus has been bared, it is divided for the entire length of the incision, immediately beyond its attachment to the tibia; and when this has been done, the deep transverse fascia which separates the superficial muscles from the deep is divided in the line of the original incision. On following inwards the deep aspect of this fascia for a short distance, the artery will be seen lying upon its deep surface, between it and the tibialis posticus. On each side of the artery there is a vena comes; the posterior tibial nerve lies on the outer side. Care must be taken not to divide the flexor longus digitorum along with the soleus, since if this is done it is possible to mistake the interosseous membrane for the deep transverse fascia, and tie the anterior tibial artery instead of the posterior. The relations of the artery at the point of ligature are shown in Fig. 291.

Ligature of the posterior tibial artery in the lower third of the leg.—*Position.*—The positions of the patient, surgeon, and assistant are similar to those in ligature of the vessel in the middle third.

Operation.—An incision 2 or $2\frac{1}{2}$ in. long is made along the line of the vessel in the lower third of the leg (Fig. 290, *b*). This divides the skin, superficial fascia, and the deep fascia, which at the lower part is somewhat thickened, owing to the transverse fibres being more developed, where it forms the internal annular ligament of the ankle-joint. The incision lies between the postero-internal border of the tibia and the inner margin of the tendo Achillis. Underneath the deep fascia the artery is found lying upon the flexor longus digitorum, surrounded by its venae comites, and having the nerve on the outer side. The needle is passed from the outer side.

Ligature of the posterior tibial artery behind the internal malleolus.—*Position.*—As for ligature of the vessel in the middle third.

Operation.—A curved incision is made in the space between the internal malleolus and the heel, the convexity being towards the prominence of the os calcis (Fig. 290, *c*). This incision is

about 2 in. in length, and in direction corresponds to the curve of the internal malleolus, but is two-thirds of an inch behind it. The skin, superficial fascia, and deep fascia, which in this situation is very much thickened to form the internal annular ligament, are divided in succession, when the artery will be found lying on the inner side of the ankle-joint, having a vena comes on the inner side, and a second vena comes and the posterior tibial nerve on the outer side. The vessel is separated from its venæ comites, and the needle passed from the nerve. If the venæ comites are very closely connected with the vessel, they may be ligatured as well.

Collateral circulation.—When the posterior tibial artery has been ligatured, the following communicating channels become dilated:—(a) Branches of the peroneal artery with branches of the posterior tibial which are given off below the point of ligature, and with the external plantar by the calcaneal and malleolar branches; (b) internal malleolar branches of the anterior tibial, with similar branches of the posterior tibial; (c) the dorsalis pedis artery and its branches, with the internal and external plantar arteries.

The peroneal artery.—This vessel is a branch given off from the posterior tibial, a short distance below its commencement.

It runs downwards, lying behind the fibula, and covered by the flexor longus hallucis muscle. In the lower part of the leg it becomes much smaller, and gives off its malleolar and calcaneal branches.

A ligature may be applied to the vessel in the middle of the calf.

Position.—The patient is placed in a semiprone position, lying upon the side which is not to be operated upon. The leg is slightly flexed at the knee, and the limb lies with the external aspect before the operator.

Operation.—The postero-external border of the fibula is defined with the fingers, and an incision 3 in. long made in the middle of the leg over this border of the bone (Fig. 292). When the skin and fasciæ have been divided, the outer border of the soleus muscle will be exposed. This muscle is retracted, and, if necessary, its attachment to the fibula in the upper part

FIG. 292. — Ligature of peroneal artery. a. Position of external incision.

of the wound cut through. By this means the origin of the flexor longus pollicis from the fibula is laid bare. This is separated from the bone until the artery is exposed, lying in a canal of fibrous tissue between the inner part of the flexor longus hallucis and the tibialis posticus. The needle may be passed from either side.

The anterior tibial artery.—This vessel commences at the lower border of the popliteus muscle, and terminates in front of the ankle-joint, where it becomes the dorsalis pedis.

Its course is marked out by drawing a line from a point which is half-way between the prominent portion of the external tuberosity of the tibia and the head of the fibula, to a point midway between the two malleoli.

In its course downwards it lies upon the interosseous membrane for the upper two-thirds, and on the tibia and the ankle-joint below this level. It lies in relation with the tibialis anticus on the inner side, and on the outer side it has the extensor longus digitorum at first, and lower down is separated from this muscle by the extensor longus hallucis. The tendon of the latter crosses the artery below. The anterior tibial nerve lies chiefly on the outer side, although, for a short distance, it may lie in front. The artery is accompanied by two venæ comites.

The anterior tibial artery may be ligatured at the upper, middle, or lower thirds of the leg.

Ligature of the anterior tibial artery in the upper third.—*Position.*—The patient is placed in the dorsal position, the leg being rotated inwards with the foot fully extended. The surgeon stands on the outer side of the limb and the assistant on the opposite side.

Operation.—An incision 3 or 4 in. long is made in the line of the artery, commencing above at the level of the tubercle of the tibia (Fig. 293, *a*). The skin, superficial and deep fascia, are divided, and the interval between the tibialis anticus and the extensor longus digitorum defined. This interval can usually be felt by the finger as a slight depression in the line of the incision. At this stage the foot is flexed, so as to allow these muscles to

FIG. 293.—Position of limb and lines of skin incisions in ligature of anterior tibial artery.

- a.* Upper third.
- b.* Middle third.
- c.* Lower third.

be separated with retractors. Upon the anterior surface of the interosseous membrane, and a short distance to the outer side of the tibia, the artery will be found, having a vena comes on each side and the nerve on the outer side. The vessel is separated from the nerve, and, if possible, from the venæ comites, and the needle passed from the outer side.

Ligature of the anterior tibial artery in the middle third.

—*Position*.—This is the same as for ligature in the upper third.

Operation.—An incision 3 in. long, whose central point corresponds to the mid point of the leg, is made in the line of the artery (Fig. 293, *b*). This incision divides the skin, superficial and deep fasciæ, and exposes the muscles. An interval between the tibialis anticus and the extensor longus digitorum is defined (it can generally be felt with the finger, or may appear as a slight depression of a somewhat yellowish tint), and these muscles are separated and retracted. The extensor longus hallucis is next met with, overlapping the vessel from the outer side; it in turn is pulled aside, and the artery will be exposed. In the middle third of the leg the anterior tibial nerve often lies in front of the vessel, in which case it is retracted to the outer side. The needle is passed from the nerve. The venæ comites are usually included within the ligature, owing to the difficulty of separating them from the artery.

Ligature of the anterior tibial artery in the lower third.

—*Position*.—As for ligature of the vessel in the upper third, though the foot is not rotated to the same extent.

Operation.—An incision 2 to $2\frac{1}{2}$ in. long is made in the line of the artery immediately above the ankle (Fig. 293, *c*). This divides the skin, superficial fascia, and deep fascia, which in this situation is considerably thickened to form the transverse portion of the anterior annular ligament of the ankle. Underneath the deep fascia the tendons of the tibialis anticus and the extensor longus hallucis are defined, the former being surrounded with a synovial sheath, and lying in a separate compartment beneath the annular ligament. The tendon of the extensor longus hallucis is drawn to the outer side, when the artery will be exposed as it lies upon the tibia. The nerve lies on the outer side. The nerve is drawn aside, and the needle passed from the outer side.

Collateral circulation.—(*a*) The external malleolar and inferior muscular branches of the anterior tibial, with the external malleolar and calcaneal branches of the peroneal artery; (*b*) the internal malleolar branch of the anterior tibial,

with a similar branch from the posterior tibial; (c) muscular, tarsal, and metatarsal branches of the *dorsalis pedis*, with the terminal branches of the anterior peroneal; (d) the *dorsalis pedis*, with the internal and external plantar arteries.

The *dorsalis pedis* artery.—The *dorsalis pedis* artery is the continuation of the anterior tibial, and extends from the ankle to the sole, where it joins the external plantar.

Its course is marked out by taking a line from the central point between the two malleoli to the base of the first inter-metatarsal space.

It lies upon the dorsal surface of the tarsus, between the tendon of the *extensor longus hallucis* on the inner side, and that of the *extensor longus digitorum* on the outer side.

Position.—The patient lies in the dorsal position, with the sole resting upon the table; the surgeon stands on the outer side of the limb. One assistant holds the foot in a state of complete extension, and the other stands opposite the surgeon and retracts the margins of the wound.

Operation.—An incision from 1 to 2 in. long is made on the dorsum of the foot in the line of the vessel, commencing about 1 in. below the ankle-joint at the lower margin of the inferior portion of the anterior annular ligament (Fig. 294). The incision is situated between the tendons of the *extensor longus hallucis* and the *extensor longus digitorum*, and divides the skin and superficial and deep fasciæ, when the artery will be exposed lying upon the bone and surrounded by a variable quantity of fatty tissue. The nerve lies externally, and the needle is passed from the outer side.

Collateral circulation.—This is established through the communications of the terminal portion of the vessel with the deep plantar arch.

The internal iliac artery.—The internal iliac trunk extends from the sacro-lumbar articulation almost to the upper border of the great sacro-sciatic foramen. It is one of the two terminal divisions of the common iliac artery.

It lies upon the anterior aspect of the lateral mass of the sacrum, from which it is separated by the lumbo-sacral cord. The corresponding vein lies to the inner side and behind, whilst

FIG. 294.--Ligature of the *dorsalis pedis* artery. *a*. Position of skin incision.

externally it has the inner margin of the psoas magnus muscle. The ureter lies upon its commencement, and the peritoneum and intestines cover it in front.

Position.—As for ligature of the common iliac artery.

Operation.—An incision about 4 in. long is made in the linea alba, commencing a short distance above the pubic symphysis. The peritoneal cavity is opened, and the intestines and great omentum pushed aside and held out of the way by flat sponges and large retractors or by the hands of an assistant. The point of division of the common iliac is defined, and from this the internal iliac artery is traced as it lies upon the front of the sacrum. The peritoneum over it is divided freely, and the vessel separated from the ureter and the sympathetic plexus which surrounds it. The aneurysm needle is passed from the inner side so as to avoid injury to the vein, which is usually of large size.

Collateral circulation.—(a) Ilio-lumbar with the deep circumflex iliac; (b) the lateral sacral with the middle sacral and the lateral sacral of the opposite side; (c) the gluteal with the deep circumflex iliac and the ascending branch of the external circumflex; (d) the internal pudic and obturator arteries, with similar vessels of the opposite side; (e) the obturator artery, with the internal circumflex and the sciatic; (f) the hæmorrhoidal branch of the inferior mesenteric with the hæmorrhoidal branches of the internal iliac.

The sciatic and internal pudic arteries.—Both these vessels are terminal branches of the anterior division of the internal iliac, and are given off from this vessel as it lies upon the anterior surface of the pyriformis muscle, just before the latter leaves the pelvis. They emerge from the pelvis through the great sacro-sciatic foramen at the lower border of the pyriformis. The sciatic artery is more superficial at the point of emergence, whilst the internal pudic lies on the inner side.

The point where these vessels come out from the pelvis is marked on the surface by trisecting a line drawn from the posterior superior iliac spine to the outer part of the ischial tuberosity; the junction of the middle and lower thirds of this line is the point required.

Position.—The patient is placed on the sound side in the semiprone position, with the legs hanging over the end of the table. The surgeon stands on the side to be operated upon and the assistant on the opposite side.

Operation.—The point of emergence of the vessels is marked out, and then an incision 4 in. long, whose centre corresponds

to the point of emergence, is made in the line of the fibres of the gluteus maximus (Fig. 295, *a*). The skin, superficial and deep fasciæ are divided; then the muscle is incised or its fasciculi separated for the entire length of the wound, and the margins well retracted till the pyriformis is exposed at the bottom of the wound. The lower border of this muscle is defined and traced inwards to the sciatic foramen, when the artery will appear. When dividing the gluteus maximus, a large muscular branch of the sciatic artery may be cut across, in which case it will serve as an easy guide to the main vessel, if it is traced inwards. The internal pudic artery lies upon the ischial spine, somewhat internal to the sciatic artery, and at a slightly deeper level. In each case the artery is separated from the adjacent structures, and the needle passed from the inner side. In the case of the internal pudic artery, care must be taken to avoid including within the ligature the pudic nerve, which lies immediately internal to the vessel.

The gluteal artery.—This vessel is the terminal branch of the posterior division of the internal iliac. It passes out from the pelvis through the upper part of the great sacro-sciatic foramen at the upper border of the pyriformis, and is accompanied by two venæ comites and the superior gluteal nerve.

Just beyond its point of emergence it subdivides into superficial and deep portions, and on this account it is necessary to apply the ligature close to the margin of the foramen. The gluteal artery emerges from the pelvis at a point corresponding to the junction of the inner and middle thirds of a line joining the posterior superior iliac spine and the top of the great trochanter, the thigh being rotated inwards.

Position.—This is the same as for ligature of the sciatic artery.

Operation.—An incision from $3\frac{1}{2}$ to $4\frac{1}{2}$ in. long is made parallel with the fibres of the gluteus maximus, the centre of the incision corresponding to the point of emergence of the

FIG. 295.—Ligature of the gluteal, sciatic, and internal pudic arteries.

- a.* Incision for sciatic and internal pudic.
- b.* Incision for gluteal.

artery from the pelvis (Fig. 295, *b*). The skin, superficial fascia containing a number of cutaneous nerves, and deep fascia are divided, and the gluteus maximus exposed. The fasciculi of this muscle are separated until the fascia which lies between it and the gluteus medius and piriformis becomes visible. An interval between the two latter muscles is then sought for, and when found the muscles are separated along this line until the sacro-sciatic foramen is reached. The gluteal artery can then be felt against the bony margin of the foramen as a distinct rounded structure. Whilst separating the fibres of the gluteus maximus, a large muscular branch of the gluteal artery may become visible, in which case it is traced onwards until it joins the main trunk. When the position of the gluteal artery has been made out, the gluteus medius and piriformis are held well aside with retractors; the artery is separated from the superior gluteal nerve and the venæ comites, and then the needle is passed from the nerve.

CHAPTER XXII.

OPERATIONS UPON THE VEINS.

General considerations.—The remarks which were made under this heading in the previous chapter, in connection with the arteries, apply for the most part to the veins.

The instruments which are necessary are the same as for the ligature of an artery.

• **The internal jugular vein.**—This vein is the chief vessel by which blood is returned from the interior of the cranium to the general circulation. It commences at the base of the skull at the lower border of the jugular foramen, by the union of the inferior petrosal and lateral sinuses as they emerge from the cranial cavity. It passes down the neck, lying in the carotid sheath of the deep cervical fascia, on the outer side of the internal carotid above the level of the thyroid cartilage, and below this level on the outer side of the common carotid. Behind the outer part of the sterno-clavicular articulation it joins the subclavian vein of the corresponding side, the two together forming the innominate vein.

The course of the vein is marked out on the surface, after placing the patient in the dorsal position with the head turned towards the opposite side, by drawing a line from the lower border of the external auditory meatus above to the outer part of the sterno-clavicular articulation below.

Indications.—The internal jugular vein has been ligatured for injuries, on account of involvement in inflammatory and malignant growths, and in cases of thrombosis of the lateral sinus, the object of the operation in the latter case being to prevent septic material from reaching the general circulation by this route.

Position.—The patient is placed in the dorsal position, with the shoulders raised by a pillow, and the head turned towards the opposite side. The operator stands on the affected side of the patient and the assistant opposite to him.

Operation.—An incision 3 in. in length is made in the line of the vessel, commencing above at the level of the apex of the mastoid process (Fig. 296). The skin, superficial fascia containing the platysma, external jugular vein, and superficial nerves, and the deep fascia are divided, and the sterno-mastoid muscle exposed along its anterior margin. The sterno-mastoid is retracted outwards, and the fascia which forms its sheath posteriorly incised, the spinal accessory nerve being avoided. The posterior belly of the digastric muscle will now be seen crossing the bottom of the wound obliquely. This structure is pulled upwards with a retractor, and then a sheath of deep cervical fascia, which incloses the internal jugular vein, will be exposed. This fascial sheath is opened on the outer side, the vein is separated from the sheath for about one-third of an inch, and an aneurysm needle passed unthreaded from the inner side.

FIG. 296.—Position of patient, and line of incision in exposure of internal jugular vein.

The vagus nerve lies behind and internal to the vein, and must be avoided in passing the ligature, and the internal carotid artery immediately internal. The hypoglossal nerve or its descendens cervicis branch may be met with at the lower border of the digastric muscle, in which case the former is drawn upwards and the latter inwards.

• **Exposure or ligature of the lateral sinus.**—The lateral sinus may become the seat of inflammation and thrombosis, owing to the extension of septic affections from the mastoid process, in cases of disease of this portion of the temporal bone. The portion of the sinus which is usually involved is that part which lies in the groove of the mastoid portion of the temporal bone. The course of the sinus is demarcated by drawing a line from

the external occipital protuberance to the anterior border of the base of the mastoid, on a level with the external auditory meatus. The sinus is usually exposed as it lies in connection with the mastoid process.

Special instruments.—A medium-sized trephine, a periosteal elevator, a chisel and mallet, and gouge.

Position.—The patient is placed in the dorsal position, with the head near the end of the table and turned toward the sound side. The operator stands on the affected side of the head and the assistant opposite to him.

Operation.—A curved incision about 2 in. in length is made parallel to the posterior free border of the external auricle. The incision is somewhat semicircular in shape, the convexity looking backwards, and the central point opposite the line of the sinus (Fig. 254, *b*, p. 360). The first cut divides everything down to the surface of the bone, including the periosteum, and when this has been done a flap is separated with a periosteal elevator. In the upper part of the incision the lower and posterior fibres of the temporal muscle will be divided, and the insertion of the sterno-mastoid separated from the base of the mastoid process. When this flap has been turned forwards, the posterior margin of the wound is retracted backwards, and then a circle of bone is removed with the trephine. The pin of the trephine is placed a little above the central point of the base of the mastoid process. Great care is necessary in this stage of the operation, as the bone is usually of varying thicknesses in different parts of the circle, and the sinus is easily opened with the trephine before the bone has been cut through all round. Many surgeons discard the use of the trephine altogether for this operation, and remove the requisite amount of bone with the mallet and chisel, or gouge. In thrombotic cases, however, injury of the sinus in removal of bone is of no moment, since the lumen of the blood vessel has already been occluded, as the result of the pathological process. When the bone has been removed, the sinus will be visible in the bottom of the wound, and can then be further dealt with as the circumstances of the case demand.

. **Varicose veins.**—This condition is most frequently met with in the superficial veins of the lower extremity, especially in the internal and external saphenous veins and their tributaries. The internal saphenous vein commences on the inner side of the dorsum of the foot, passes upwards in front of the internal malleolus on the inner side of the leg and the knee, and terminates by passing through the saphenous opening in the fascia

lata of the thigh and joining the common femoral vein. The external saphenous vein commences on the outer side of the dorsum of the foot, passes upwards behind the external malleolus, runs along the middle of the calf, and finally perforates the deep fascia in the lower part of the popliteal space, and joins the popliteal vein.

The operation which appears to be the most efficient is the following :—

Operation.—Short incisions are made with the scalpel, in succession, over the most enlarged parts. The dilated portion of the vein is separated by careful dissection from the surrounding fascia for about 1 in. or more, if the “knot” is very large, and two fine silk ligatures are applied at the extremities of the exposed part. The portion of vein which lies between these ligatures is excised, and the incisions in the skin closed carefully with fine silk sutures, and an aseptic dressing applied.

Venesection.—The operation of venesection or “bleeding” is only occasionally performed at the present day.

According to Mr. Jacobson, the operation is indicated in the following clinical conditions, namely—

(a) In some cases of pneumonia of traumatic origin, when the patient is a “full-blooded” person, and the affection extends rapidly.

(b) In some cases of chronic bronchitis, when the action of the heart is much impeded owing to the right side of the organ being much distended and engorged with blood.

(c) In certain cases of impending apoplectic seizures, where a tendency to the occurrence of this condition exists.

(d) In the treatment of some forms of aneurysm, especially when they are intrathoracic.

When the operation of venesection is considered necessary, from 8 to 10 oz. of blood are removed in the following manner, and in many cases it will be found necessary to repeat the procedure. In the treatment of aneurysms only small quantities are removed, just sufficient to reduce excessive action of the heart.

Special instruments.—A small scalpel or a bleeding-lancet, a bandage, a bleeding-bowl, an aseptic pad, and a small narrow bandage.

Position.—The patient is placed in the sitting position, the arm hanging over the side of the chair. The surgeon stands on the outer side of the limb upon which he proposes to operate.

Operation.—A superficial vein is chosen, which is of moderate size, and can easily be dealt with. In most cases the median basilic or the median cephalic vein of the arm is selected. The

vein in this situation is quite superficial, and in addition to receiving the blood from the anterior aspect of the forearm, it has a wide communication with the deep veins in the antecubital fossa, by means of the deep median vein.

A bandage is applied to the middle of the upper arm, and tied sufficiently tightly to stop the circulation in the veins, but to still allow the flow of blood along the arteries. A roll of paper, a bandage, or a piece of wood is placed in the hand of the patient, and he is told to grasp it during the operation. This serves to divert the attention of the patient, as well as to force the blood of the limb into the superficial veins. The median basilic or the median cephalic vein is then chosen, whichever is the more prominent, care being taken to avoid any abnormal artery which may be given off from the brachial and lie in the superficial fascia at the bend of the elbow.

The thumb of the surgeon's left hand is placed on the selected vein a short distance beyond the point which is to be punctured, so as to control the flow of blood. A bleeding-lancet or a sharp scalpel is then taken in the right hand, and grasped between the finger and thumb in such a manner that only about half an inch of the blade projects. A small cut, about half an inch in length, is then made with one sweep of the blade, dividing the skin, fascia, and anterior wall of the vein. Care must be taken not to penetrate the posterior wall of the vein, in which case it would be possible to damage one of the adjacent arteries. If the first cut does not extend into the lumen of the vein, a second one is made in a similar manner, but the opening in the skin and in the fascia must be larger than that in the vein.

When the vein has been opened, a bleeding-bowl is placed beneath the elbow, the left thumb is removed from the surface of the vein below, and the stream of blood allowed to flow until the requisite amount has been removed. During the evacuation of the blood the affected limb should not be moved, so as to avoid entrance of the blood into the surrounding subcutaneous tissue.

The necessary amount of blood having been removed, the left thumb is placed upon the opening in the vein, and the bandage from the upper arm taken off. A small aseptic pad of lint is next placed upon the wound, and fixed in position by the narrow bandage, which is applied in the figure-of-eight fashion.

This dressing is kept on for two or three days, and then discontinued. The limb ought to be kept in a sling for a few days longer.

If the artery is injured at the time of the operation, it may

be followed by the formation of an arterio-venous aneurysm, owing to the establishment of a communication between the lumen of the vein and that of the artery.

Intravenous injection of saline fluids.—The intravenous injection of saline fluids, especially sodium chloride 0·75 per cent. in sterilised water, has been practised with success in a number of cases. The indications for this proceeding appear to be the following, namely—

1. Acute anæmia, dependent upon the following causes :—

(a) Severe hæmorrhage after an accident, such as the cutting off of a limb in a railway smash, or after attempted suicide or homicide, when a large vessel has been severed, in cases of “cut throat,” etc.

(b) Severe loss of blood during a surgical operation.

(c) Severe loss of blood in connection with parturition, as in placenta prævia, adherent placenta, accidental hæmorrhage, and post-partum hæmorrhage.

It ought to be borne in mind, that unless the bleeding points have been securely ligatured, injection will only tend to restart the hæmorrhage.

2. In some cases of shock and collapse, when the action of the heart is very weak, and there is impending dissolution.

It is only in occasional cases of this kind that the injection of a saline fluid can be expected to be of much benefit.

Special instruments.—Elastic rubber tube, fine scalpel, fine-pointed dissecting forceps, aneurysm needle, cannula introducer (Fig. 297, 'a), injection apparatus with cannula (Fig. 297, 'b), needle, needle-holder, and ligature material.

Preliminary preparations.—Three to six pints of water are boiled in order to render it sterile. Then a sufficient quantity of sodium chloride is added to make the solution of a strength of 0·75 per cent. (a drachm to a pint is sufficiently approximate for practical purposes).

The solution thus prepared is kept at a temperature of 99° to 100° F.

Immediately before the apparatus is used it is washed out with hot sterilised water, and then filled with the saline fluid.

Operation.—The vein to be opened having been decided upon (the median basilic or the median cephalic, just above the bend of the elbow, is most convenient, though in very anæmic persons it may be necessary to expose one of the deep veins of the arm), the elastic rubber tube is wound round the limb on the proximal side of the vein. An incision is made through the skin along the course of the vein, and this structure is dissected free from

the surrounding fascia for a distance of an inch. The vein lies in the superficial fascia, and embedded in fatty tissue. A silk ligature is passed with the aneurysm needle underneath the vein at each extremity and in the middle of the incision. The distal ligature is then tied.

The anterior wall of the exposed vein is picked up with the fine forceps and a small valvular incision made into it with the point of the scalpel. The cannula introducer (Fig. 297, *a*) is now taken and passed into the interior of the vein towards the

FIG. 297.—Apparatus for the intravenous injection of fluids.

a. Cannula introducer. *b.* Injection apparatus. The cannula is inserted into a vein of the recipient, and the reservoir is filled with the fluid which it is wished to inject. Pressure is obtained by raising the reservoir to a suitable height above the patient. The thermometer is to indicate the temperature of the fluid which is being injected.

proximal side. The cannula of the injection apparatus (which has already been filled with fluid) is passed into the vein on the grooved under aspect of the introducer. The cannula introducer is withdrawn, and the middle silk ligature tied around the neck of the cannula. The elastic rubber tube is now removed. The stopcock of the injection apparatus is turned on, the reservoir gradually raised by an assistant, and a sufficient amount of fluid allowed to flow into the vein. Usually two to four pints will be found to be sufficient.

The upper ligature is now tied above the point of the cannula, and the instrument withdrawn. The incision is sponged dry

and closed by the insertion of one or two points of interrupted silk sutures.

Transfusion.—By this term is understood the transference of blood from one individual to another. It may be accomplished directly by making a connection between the lumen of one of the veins of the “receiver,” and that of one of the “giver.” (The individual who receives the blood is known as the “receiver,” and the individual from whom it is taken, the “giver.”) This is called the *direct* method of transfusion: the *indirect* method is, when blood is taken from an individual, defibrinated, and then injected into the vein of the “receiver,” according to the method described in the preceding operation.

Direct transfusion.—For this purpose the instrument illustrated in Fig. 298 will be found most convenient.

The veins of the “giver” and “receiver” are exposed in the manner

FIG. 298.—Apparatus for direct transfusion. It consists of two glass or metal cannulae with stopcocks, and connected by a rubber tube, in the middle of which is a dilatation which serves as an injection pump.—
A. VELLING.

described above, and a cannula inserted into each. Before inserting the cannulae they should be filled with a warm solution of sodium chloride. The rubber reservoir is then filled with a similar solution, and the extremities of the tube fixed to the cannulae. The stopcocks are turned on, and the tube on the side of the “giver” pinched by an assistant. The rubber reservoir is then compressed, so as to drive the fluid in its interior into the vein of the “receiver.” Next, the tube on the side of the “receiver” is compressed, that on the side of the “giver” relaxed, and the reservoir allowed to expand, and become filled with blood. The tube on the side of the “giver” is then compressed, that on the side of the “receiver” relaxed, and the reservoir again forcibly compressed.

This proceeding drives the blood within the reservoir into the veins of the “receiver.” The reservoir is usually made to contain 2 drms. This alternate compression and relaxation is repeated until a sufficient amount of blood has been transferred from the veins of the “giver” to those of the “receiver.”

CHAPTER XXIII.

OPERATIONS UPON NERVES.

THE surgical operations which are performed upon the nerve trunks or branches in their continuity may be divided into five groups :—

- (a) Suture of divided nerves, or neurorrhaphy.
- (b) Nerve stretching.
- (c) Division of a nerve, or neurotomy.
- (d) Excision of a portion of a nerve, or neurectomy.
- (e) Excision of ganglia.

In order to perform these different operations, it is necessary, in the first place, to fully expose that portion of the nerve trunk upon which it is proposed to operate. In this chapter the general principles to be observed in performing these operations will be first described, and afterwards the methods of exposing the individual nerve trunks.

General considerations.—Operations upon nerve trunks are generally necessary either on account of an injury to a nerve or to the adjacent tissues, or owing to the formation of a tumour in connection with a nerve, or the involvement of a nerve by the extension of a malignant growth from the neighbourhood. Occasionally it is necessary to divide the sensory nerve supplying an organ which has become the seat of a malignant growth, as in epithelioma of the tongue, in order to relieve the excessive pain from which the patient is suffering. Division or even excision of a portion of a sensory nerve may be required in some cases of intractable neuralgia. Motor nerves may require division in some cases of severe muscular contraction, depending upon an affection of the nerve or of the corresponding nervous centre, as in some forms of wryneck, when it may be necessary to divide the spinal accessory nerve.

Whenever a nerve trunk has been divided by an injury, it is advisable to expose the severed ends and make an attempt to unite them.

Nerve ganglia, such as the Gasserian ganglion, have been excised with the view of curing intractable neuralgias, which have proved non-amenable to less severe forms of treatment.

Primary tumours of nerves are not common, but neuromata, either true or of the nature of fibrous tumours, occur and require treatment.

It occasionally happens that a nerve trunk becomes involved in the callus formed in the repair of a fractured bone, in which case it may be necessary to expose the nerve, in order to free it from the new-formed tissue in which it has become embedded, or by which it has been pressed upon.

Suture of a divided nerve, or neurorrhaphy.—This pro-

FIG. 299.—Primary suture of a divided nerve.

- a. Divided nerve with lacerated extremities.
- b. Extremities pared and sutures inserted ready for tying.
- c. Ends approximated and sutures tied.

cedure is rendered necessary when a nerve trunk has been divided by accident or otherwise. If the divided ends of the nerve are united by an operation, performed immediately after the division has occurred, it is called “immediate suture,” while if this is not done until some time afterwards the term “secondary suture” is applied.

Immediate suture.—In union of a nerve by immediate suture, the nerve is sought for in the wound, and the two ends freely exposed; and if there has been any laceration or bruising of the divided nerve, the irregular tags are cut away, so as to leave two clean ends which can be easily brought into exact apposition. When there has been much laceration, and it is found requisite

to remove a portion of the nerve trunk, it may also be necessary to free each of the divided ends for a short distance so as to facilitate their approximation. The two ends are next fixed in apposition by the introduction of several sutures of fine silk or catgut, the number of sutures varying according to the size of the nerve. A rounded needle or a small Hagedorn's needle is used for the introduction of the sutures. Each suture is passed through the entire nerve substance, about a third of an inch from the cut surface of each extremity, all the sutures being introduced before any are tied. When sufficient sutures have been put in, they are carefully tied and the ends cut short. The sutures must not be tied too tightly, or they will cut out; it is sufficient to tie them in such a manner that the cut surfaces are fixed in approximation. When this has been done, it is advisable if possible to put in several fine sutures through the fibrous tissue forming the sheath of the nerve. When the two ends of the nerve have been united in this way, the entire wound is thoroughly cleansed, and closed with sutures in the usual manner. Care should be taken to approximate the tissues in the deep part of the wound, especially in the neighbourhood of the injured nerve, so as to avoid any undue tension which might tend to separate the sutured nerve-ends. In order to effect this, it will be found advisable in some cases to unite the deep part of the wound with several deep sutures.

Secondary suture.—In the union of a nerve by secondary suture, the divided ends are first exposed by an incision made through the overlying tissues in the long axis of the injured nerve. It is necessary in many cases to make a long incision, owing to the ends of the divided nerve having become separated or extensively involved in scar tissue.

The proximal end of the nerve is usually found to have become enlarged and bulbous, whilst the distal end is atrophied and embedded in the scar tissue. In some cases the distal end is very much shrunken, and appears as a fine thread. When considerable difficulty is experienced in locating the position of the distal end, it is advisable to expose the nerve a short distance beyond the point of division, and then to trace the trunk upwards. When the two ends of the nerve have been fully exposed, they are dissected free from the surrounding scar tissue, and cut across so as to lay bare areas of freshly cut nerve for approximation. The proximal end should be cut across just before the enlarged portion joins the healthy nerve trunk, care being taken that the section exposes healthy nerve bundles. A small portion only of the distal end is excised, generally about

one-fourth or one-third of an inch, as in most cases the nerve fibres in this portion have undergone considerable degeneration. The two ends having been prepared in this manner, they are united according to the method described in connection with "immediate suture." In cases of secondary suture there is more scar and fibrous tissue in the sheath of the nerve, and on this account it is easy to fix the two ends in apposition. When the ends have retracted, and are separated from one another by a short interval, it is necessary to free the nerve both proximally and distally for a short distance, before the two ends can be approximated without exerting undue tension. .

FIG. 300.—Secondary suture of a divided nerve.

- a.* Divided nerve with proximal end enlarged and bulbous, and distal end attenuated.
- b.* Nerve pared and sutures inserted ready for tying.
- c.* Suture completed.

If the ends of a divided nerve are embedded in much scar tissue, or the nerve has been extensively lacerated at the time of the injury, it may be impossible to bring the prepared extremities into apposition by the above procedure.

When this condition is met with, an attempt may be made to approximate the divided extremities by splitting the more healthy segment a short distance from the cut end and turning down a piece of nerve tissue. This piece is fixed to the other end, in the manner described above.

If the loss of nerve substance is so extensive that the exposed ends cannot be brought together by nerve splitting, an attempt may be made to bring about restoration of the functions of the

nerve by introducing into the gap a piece of nerve from an animal, or from the amputated limb of another patient.

Nerve-stretching.—The nerve trunk which it is desired to stretch having been fully exposed, according to the methods described in connection with individual nerves, it is carefully separated from the surrounding tissue and lifted up in the wound. In the case of the large nerves, such as the great sciatic, the finger and thumb are used for stretching, whilst in the case of small nerves a blunt hook of suitable size will be found most convenient (Fig. 301). When the nerve has been seized with the finger and thumb, or a hook has been placed underneath it, steady tension, gradually applied, is exerted, the amount of tension varying with the size of the nerve. Thus, when the large sciatic is being stretched, a force of 30 lb. may be exerted, while for a small nerve, such as the supra-trochlear, not more than half a pound should be employed. The tension is exerted first on the proximal portion for about two to five minutes, and then for a similar period on the distal section. When the nerve has been stretched in this manner, it is replaced in its former position, and the external wound closed.

Division of a nerve, or neurotomy.—This operation may be performed either through an open incision or subcutaneously. In the great majority of cases it is preferable to adopt the former method. The nerve trunk is exposed in the usual manner, and then cut across either with the scalpel or scissors.

Excision of a portion of a nerve, or neurectomy.—This operation is similar to the preceding, with the exception that a larger portion of the nerve is exposed, and a small piece removed by cutting through the nerve in two places, and taking away the intervening part.

Neurectomy and neurotomy are operations which are performed only on small sensory nerves, such as the supra-orbital; but large branches are divided in exceptional cases, such as cancer of the tongue and severe intractable neuralgia of the fifth nerve.

In all cases of operations upon nerves, care must be taken not

FIG. 301.—Blunt hook, suitable for stretching a small nerve.

to seize the nerve trunk with forceps or similar instruments, as this always leads to bruising of the nerve fibres.

Excision of nerve ganglia.—Removal of a nerve ganglion, together with the adjacent portions of the nerve trunk with which it is connected, has been practised for the relief of some forms of severe neuralgia which are not amenable to milder forms of treatment. The Gasserian ganglion and Meckel's ganglion have been removed for intractable neuralgia of the second or third divisions of the fifth cranial nerve. In some cases very good results have followed the performance of the operation, but the comparative value of these procedures has not yet been decided.

EXPOSURE OF INDIVIDUAL NERVES.

The fifth cranial nerve—The supra-orbital nerve.—This nerve is one of the cutaneous branches of the first division of the fifth. It passes out from the orbit through the supra-orbital foramen or notch, which can be felt at the junction of the inner with the middle third of the superior margin of the orbit.

Position.—The patient lies in the dorsal position, with his head supported by a pillow; the surgeon stands at the head of the patient and his assistant opposite to him.

Operation.—The eyebrow having been shaved, an incision not quite an inch in length is made along the supra-orbital margin, the centre being opposite to the point of exit of the nerve (Fig. 302, *a*). The skin, fascia, and fibres of the orbicularis palpebrarum muscle are divided in the line of the incision, and then the nerve will become visible, lying upon the bone just beyond the notch or foramen, in company with the supra-orbital artery. The nerve may be found to have already divided into two branches at the point where it emerges from the notch or foramen. The nerve is next separated from the vessel, and can then be stretched. Care must be taken in this operation for nerve stretching not to divide the nerve as it lies upon the bone.

The infra-orbital nerve.—The infra-orbital nerve emerges through the infra-orbital foramen, which is situated directly below the middle of the lower margin of the orbit. It passes from the spheeno-maxillary fossa along the floor of the orbit to reach the infra-orbital foramen.

Operation.—1. *Exposure of nerve on face by incision through cheek.*—The patient is placed in the same position as for exposure of the supra-orbital nerve; the surgeon stands on the affected side of the head and the assistant opposite to him.

An incision about 1 in. in length is made along the lower margin of the orbit, the centre of the incision being opposite to the foramen (Fig. 302, *b*). The skin, fascia, lower fibres of the orbicularis palpebrarum, and the attachment of the levator labii superioris are divided, and the nerve sought for where it emerges as several branches from the foramen.

2. *Exposure of nerve in infra-orbital canal.*—In order to expose that portion of the nerve which lies in the canal, the periosteum of the floor of the orbit is detached, and the contents of the orbital cavity with the periosteum lifted up and held away from the field of operation with a retractor. The thin bony plate which forms the roof of the canal in which the nerve lies, is carefully removed with a fine grooved chisel, and the nerve lifted up from its bed.

3. *Exposure of nerve from the mouth.*—The nerve may also be exposed by dividing the mucous membrane of the mouth, where it is reflected from the alveolar process on to the inner surface of the upper lip of the affected side. When this has been done, the structures which lie superficially are separated from the bone with a periosteal elevator, until the foramen is reached and the nerve exposed. The advantage of this method of operating is the absence of a visible scar.

FIG. 302.—Exposure of supra-orbital and infra-orbital nerves.
a. Incision for supra-orbital nerve.
b. Incision for infra-orbital nerve.

Removal of Meckel's ganglion, and division of the second division of the fifth nerve in the spheno-maxillary fossa.—This operation has been carried out—(*a*) Through an incision below the margin of the orbit, and then chiselling a hole through the superior maxilla, opening the antrum and extending the wound into the spheno-maxillary fossa by removing a portion of the posterior wall of the antrum; and also (*b*) by a deep dissection of the pterygoid region, after the zygoma has been exposed, divided, and turned downwards.

Removal of the Gasserian ganglion.—The Gasserian ganglion is situated within the skull between the bone and dura mater, in a depression of the middle cerebral fossa immediately behind the foramen ovale.

Indications.—Removal of the Gasserian ganglion is necessary and advisable only in those severe cases of trigeminal neuralgia which will not respond to palliative treatment, and in which the patient's life is made unbearable by the severity of the

pains along the course of the branches of the fifth cranial nerve.

Removal of Gasserian ganglion through pterygoid region.

—*Special instruments.*—As for craniotomy with the addition of a suitable retractor.

Position.—The patient is placed in the dorsal posture, with the head turned over towards the unaffected side, and supported by a firm pillow. The surgeon stands on the same side as the lesion, and his assistant directly in front of him.

Operation.—For convenience of description, this operation may be divided into the following stages :—

FIG. 303.—External incision for exposure and removal of Gasserian ganglion.

(a) *Skin incision.*—A \cap -shaped incision is made which commences a little below the anterior extremity of the zygomatic arch or malar prominence, extends upwards to the level of the external angular prominence of the frontal bone, backwards to a line prolonged upwards from a point half an inch in front of the external auditory meatus, and then downwards, so as to terminate about half an inch below the posterior part of the zygoma (Fig. 303). The flap thus marked out is turned downwards, and is made to consist of the skin and fascial layers.

(b) *Resection of the zygomatic arch.*—With a small saw the bone forming the zygomatic arch is sawn through along the

lines shown in Fig. 304. Next, the temporal fascia which is attached by two laminae to the upper part of the zygomatic arch is cut through, and the zygoma with its attached masseter muscle turned downwards. Care should be taken to make the section of the anterior part of the zygomatic arch well forwards, in order to provide sufficient room for the ready performance of the subsequent parts of the operation.

(c) *Detachment of the temporal muscle and exposure of the temporal fossa.*—The coronoid process of the lower jaw, which has been laid bare by throwing down the masseter, is sawn through along the line shown in Fig. 304. During this part of the operation, it must be remembered that the attachment of the temporal muscle extends much lower on the internal and anterior aspects of the process than on the external surface. The bone having been sawn through, the temporal muscle is turned upwards and separated from its connection with the temporal fossa by a periosteal elevator. The deep temporal arteries, branches of the internal maxillary, are met with at this stage, and, when seen, they should be ligatured and turned downwards. The sphenoidal attachments of the external pterygoid muscle are now exposed and detached with the periosteal elevator, and the muscle turned backwards. The foramen ovale and the inferior maxillary division of the fifth nerve and its branches can now be readily located by following upwards one of the exposed nerve branches.

FIG. 304.—Removal of Gasserian ganglion. The dotted lines show where the saw cuts ought to be made in the zygomatic arch and coronoid process.—ROSE.

(d) *Removal of a portion of cranial wall.*—When the exact position of the foramen has been made out, a trephine, or chisel and mallet, is taken, and a segment of the cranial wall removed from immediately behind and above this foramen, and in the position shown in Fig. 305. Previous to removal of the bone, it is usually convenient to expose the trunk of the middle meningeal artery immediately before it passes through the foramen spinosum, and to ligature it. When a trephine is used for removal of the bone, the aperture thus made should be enlarged in an internal and forward direction until it is made to com-

municate with the foramen ovale. The dura mater of the middle cerebral fossa is next separated from its connection with the bone by a periosteal elevator or a probe-pointed director, especial care being taken not to perforate this membrane and so open the subdural space.

(e) *Location and removal of the Gasserian ganglion.*—The inferior maxillary division of the fifth nerve is traced inwards from the foramen ovale until the Gasserian ganglion is reached. This is much facilitated by pressing upwards and backwards the dura mater and superjacent brain with a small spatula. When the position of the ganglion has been thus located, it is separated

by careful dissection from the dura mater, and then its connections with the sensory part of the fifth nerve cut through with a fine pair of scissors. In some cases it will be found more convenient to take away the ganglion piecemeal, using a small sharp Volkmann spoon for the purpose.

(f) *Closure of the external wound.*—All hæmorrhage is arrested by pressure, or ligature where possible, and the segment of bone removed with the trephine is replaced. Next, the coronoid process is sutured with silver wire, the zygomatic arch replaced and fixed with wire sutures, and finally the margins of the skin incision are united with salmon-gut.

FIG. 305.—Removal of Gasserian ganglion. Position of trephine hole in removal of a portion of cranial wall.—ROSE.

T. Trephine hole.
F.O. Foramen ovale.
F.S. Foramen spinosum.

Removal of the Gasserian ganglion through the temporal region.—*Position.*—The position of patient and operator and the instruments required are the same as in the previous operation.

Operation.—(a) *External incision and resection of skull wall.*—A \cap -shaped incision is made in the temporal region of the affected side, which commences above the zygoma and behind the external angular process of the frontal bone, extends upwards to the temporal crest, and downwards to a point half an inch in front and the same distance above the external auditory meatus (Fig. 306). This incision divides all the tissues down to the bone. With a surgical motor saw, or a chisel and mallet, the skull wall

is divided along the line of the skin incision, whilst at the base of the flap the soft tissues are lifted up and the underlying bridge of bone cut through. When this has been done, a \cap -shaped flap can be turned downwards, which consists of all the soft structures of the scalp and a segment of the cranial wall.

(b) *Lifting up of dura mater and superjacent brain, and ligation of middle meningeal artery.*—With a rectangular periosteal elevator the dura mater is separated from its attachment to the skull wall in the direction of the base of the skull and towards the middle line. The middle meningeal artery will be seen lying upon the dura mater and between it and the bone. The main trunk of this is followed towards the foramen spinosum by lifting upwards and inwards the dura mater and the brain. At or near the foramen spinosum, the trunk of the vessel is surrounded by two ligatures and divided between.

(c) *Exposure and removal of the Gasserian ganglion.*—The separation and lifting up of the dura mater is continued towards the median line and towards the base of the middle cerebral fossa, until the depression at the apex of the petrous portion of the temporal bone is laid bare in which the ganglion lies. By careful dissection the ganglion is separated from its attachments to the dura mater and the periosteum of the base of the skull, and the second and third branches of the fifth cranial nerve are exposed as far as the foramen rotundum and the foramen ovale. These branches are cut through close to the foramina, and the two portions of nerve and ganglion pulled in an outward direction so as to render tense the portion of nerve on the proximal side of the ganglion. When this has been done, the nerve is cut through as close to the dura mater as possible, and the ganglion with the attached portion of nerves removed.

(d) *Closure of the external wound.*—The space in the base of the skull from which the ganglion has been removed is sponged dry, and the dura mater and brain allowed to fall back into their normal position. The flap of scalp and skull wall is then

FIG. 306.—Removal of Gasserian ganglion. Position of skin incision and shape of flap which is turned down.

replaced, and the margins of the external incision united by sutures of salmon-gut.

Of these two operations, the second appears to present the most advantages, and in my opinion is the more preferable. The ganglion is effectually removed, the attachments of the muscles of mastication on the affected side are not seriously interfered with, and there is less possibility of septic complications.

The inferior dental nerve.—The inferior dental nerve enters the inferior dental foramen opposite the centre of the vertical ramus of the lower jaw, it then runs downwards and forwards in the dental canal.

Position.—The patient is placed in the dorsal position, with the head turned to the opposite side. The surgeon stands on the affected side and his assistant opposite to him.

Special instruments.—Three-quarter-inch trephine, or small gouge and mallet.

Operation.—A horizontal incision 2 in. in length is made opposite the middle of the vertical ramus of the lower jaw, not higher than the superior border of the lower alveolus. This incision divided the skin and deep fascia, and contained superficial vessels and nerves.

The margins of the incision are retracted, and the masseter divided in the direction of its fibres, and the outer surface of the vertical ramus exposed. The margins of the whole incision are then well retracted, the trephine applied to the bone, and the outer plate of bone removed.

The trephine is then removed, and, if necessary, the inferior dental canal located with the gouge. In this manner the canal can be opened and the nerve exposed either just before it enters or in the canal. The nerve is then dealt with, the bone may be replaced, and the wound closed.

This nerve may also be reached through the mouth, before it enters the inferior dental foramen, by incising the mucous membrane immediately behind this aperture, or nearer its termination by chiselling away the outer wall of the inferior dental canal in the horizontal ramus.

The results which have followed these operations do not appear to have been very favourable, and on this account it is doubtful if they can be said to be justifiable.

The auriculo-temporal nerve.—This nerve is one of the branches of the third division of the fifth. It passes upwards over the root of the zygoma in company with, and immediately behind, the superficial temporal artery.

It can be exposed by an incision similar to that described for the superficial temporal artery (p. 382, Fig. 268, *b*).

The lingual nerve.—The nerve is also a branch of the third division of the fifth.

It can be exposed as it lies underneath the mucous membrane of the floor of the mouth, about half an inch below and behind the last molar tooth of the lower jaw, and also in the upper part of the incision which was described for ligature of the lingual artery (see p. 379). In the latter case the nerve will be found lying upon the hyoglossus, a short distance above the hypoglossal nerve.

Operation (through the mouth).—The patient is placed in the dorsal position, the mouth being held open with a gag, and the tongue drawn to the opposite side. The surgeon stands in front of the open mouth.

The nerve can generally be felt with the finger, as it lies underneath the mucous membrane. An incision about 1 in. in length is made through the mucous membrane on the floor of the mouth, in an antero-posterior direction, and situated about half-way between the side of the tongue and the inner surface of the jaw. With a blunt hook the nerve is lifted up from the connective tissue which surrounds it, and may be divided with a pair of scissors, or a small portion may be excised.

The facial (seventh cranial) nerve.—This nerve issues from the cranium through the stylo-mastoid foramen, and then passes downwards and forwards in the substance of the deep part of the parotid gland. It can be exposed immediately beyond its point of emergence.

Position.—The patient lies on the back, with the head turned over towards the unaffected side. The surgeon stands on the affected side of the patient, and his assistant opposite him.

Operation.—An incision about $1\frac{1}{2}$ in. in length is made, commencing above at the anterior margin of the mastoid process and opposite the external auditory meatus, and extending downwards to a point just behind the angle of the lower jaw. The skin, superficial and deep fasciæ are divided, and the anterior border of the sterno-mastoid and the posterior margin of the parotid gland exposed. The former is retracted backwards, and the latter forwards. On dividing the connective tissue between these two structures, the posterior belly of the digastric muscle will become visible. This is drawn downwards, and then the facial nerve will be found in the upper part of the wound. In this position the nerve is surrounded by dense fascia, and careful dissection is necessary to expose it without injury. The posterior

auricular artery and vein may be met with, in which case they are drawn aside with a retractor.

The spinal accessory (eleventh cranial) nerve.—The spinal accessory nerve emerges from the cranium through the middle compartment of the jugular foramen in company with the vagus. From this point it passes in a downward and backward direction, crossing the internal jugular vein and the transverse process of the atlas, until it reaches the anterior border of the deep portion of the sterno-mastoid muscle, which it enters at the junction of the upper with the second fourth. It emerges from this muscle a little below the junction of the upper with the middle third, and then crosses the posterior triangle to reach the trapezius, into the deep aspect of which it enters. The

FIG. 307.—Exposure of spinal accessory nerve.
Position of skin incision.

nerve can be exposed either before or after it pierces the sterno-mastoid muscle. The operation for exposure of the nerve is usually undertaken for wry-neck, in which case the nerve must be laid bare above the point at which it enters the sterno-mastoid.

Position.—The patient is placed in the dorsal position, with the head and shoulders slightly raised by means of a pillow, and the head turned towards the unaffected side and thrown slightly backwards.

Operation.—An incision about $2\frac{1}{2}$ in. long is made along the anterior border of the sterno-mastoid, commencing above at the apex of the mastoid process (Fig. 307). The skin, superficial fascia, and deep fascia are divided for the entire length of the incision, by which means the external surface of the sterno-mas-

toid is exposed. The anterior border of this muscle is defined, and the head is bent forwards a little so as to allow of retraction of the muscle and exposure of the fascial sheath behind. When this has been done, the posterior part of the sheath is divided in the line of the original incision, and the nerve carefully sought for as it enters the muscle. The nerve can often be felt as a rounded cord immediately below and external to the transverse process of the atlas. If the nerve is not readily found, the inferior border of the posterior belly of the digastric muscle should be defined, and the nerve sought for in the space between this muscle and the sterno-mastoid. The fascia in this region is dense, and careful dissection is necessary.

Union of facial and spinal accessory nerves.—*Indication.*—This operation has been adopted in cases where a permanent destructive lesion of the facial nerve exists on the intracranial side of the stylo-mastoid foramen—the aperture of exit of the facial nerve from the skull.

Operation.—An incision $2\frac{1}{2}$ in. long is made, commencing at the apex of the mastoid process and extending downwards along the anterior border of the sterno-mastoid muscle. The facial and spinal accessory nerves are sought for, as described in the two preceding operations, and the spinal accessory nerve divided close to its entrance into the sheath of the sterno-mastoid muscle posteriorly, then turned forwards and united to the facial nerve. The wound is then closed and dressed.

The great occipital nerve.—This nerve is a cutaneous branch of the posterior division of the second cervical, and passes into the scalp through the outer margin of the trapezius muscle where this is attached to the superior curved line of the occipital bone.

Operation.—The patient lies in the same position as for exposure of the spinal accessory nerve, but with the head bent downwards towards the chest.

An incision about $1\frac{1}{2}$ in. long is made parallel with the superior curved line of the occipital bone, commencing a short distance outside the external occipital protuberance. The skin and fasciæ are divided, and then the nerve will become visible lying above and internal to the interval between the sterno-mastoid and trapezius, and on the mesial side of the occipital artery. The surrounding fascia is very dense; on this account care must be taken not to divide the nerve where it lies close to the bone.

The brachial plexus.—The brachial plexus lies in the posterior triangle of the neck and the upper part of the axilla, and extends as far as the apex of the coracoid process, where it

terminates by dividing into its various branches. It is composed of the anterior primary divisions of the lower four cervical nerves, together with the greater part of the anterior division of the first dorsal, and a small branch from the fourth cervical. At its commencement it lies between the anterior and the middle scalene muscles.

Position.—The patient is placed in the dorsal position, with the shoulders raised, the head turned towards the unaffected side, and the arm drawn well down by the side of the body. The operator stands on the affected side of the patient, and the assistant on the opposite side.

Operation.—An incision about 3 in. in length is made, commencing above at the outer margin of the sterno-mastoid, at the level of the notch in the thyroid cartilage, and extending downwards to a point a short distance above the centre of the clavicle. The skin and superficial fascia with the platysma are divided, and the external jugular vein defined. It is necessary in most cases to ligature this vessel in two places, and divide it between, but occasionally it can be drawn aside. The deep fascia is next divided for the entire length of the incision, the supraclavicular nerves being avoided if possible. In the lower part of the wound the posterior belly of the omo-hyoid muscle will be exposed, and at the inner margin the outer border of the scalenus anticus. The former muscle is drawn downwards, and the fascia carefully separated from the cords of the plexus as they appear at the outer margin of the scalenus anticus. The superficial branch of the transverse cervical artery, and its accompanying vein, lie in front of the plexus in the outer part of the incision.

The musculo-spiral nerve.—This nerve is given off from the posterior cord of the brachial plexus opposite the coracoid process. From this point it first passes downwards behind the axillary artery, and at the upper part of the arm it begins to wind outwards in the musculo-spiral groove, in company with the superior profunda artery. In the lower third of the arm it pierces the external inter-muscular septum, and lies in front of the brachialis anticus, overlapped by the supinator longus. The nerve may be exposed in the musculo-spiral groove, and also in the lower third of the arm where it lies upon the brachialis anticus.

(a) *In the musculo-spiral groove.*—*Position.*—The patient lies in the dorsal position; the upper arm is placed vertically, the elbow is fully flexed, and an assistant holds the limb in this position (Fig. 308). The operator stands on the affected side and his assistant at his left hand.

Operation.—An incision 3 in. in length is made in the middle third of the posterior aspect of the upper arm, parallel with the long axis of the limb. The skin, superficial fascia, and deep fascia are divided for the whole length of the incision, and the triceps muscle exposed. This structure is divided in a vertical direction until the musculo-spiral groove is reached, when the nerve will be found lying upon the bone in company with the superior profunda vessels. The nerve is separated from the artery, and may then be treated by whatever special method is thought advisable. If care is not taken in the later stages of the operation, the nerve may be divided as it lies upon the humerus.

FIG. 308.—Position of patient, and lines of external incisions, in exposure of musculo-spiral nerve in the musculo-spiral groove, and of ulnar nerve behind the internal condyle of the humerus.

a. Musculo-spiral. b. Ulnar.

(b) *In front of the arm above the bend of the elbow.*—Position.

—The arm is placed at right angles to the side, supinated, slightly flexed at the elbow, and supported on a table.

Operation.—An incision is made, about 3 in. in length, commencing an inch above a point one-third of the distance from the external to the internal condyle of the humerus, and extending upwards parallel with the outer margin of the biceps

FIG. 309.—Position of limb, and lines of external incisions in exposure of musculo-spiral nerve above the bend of the elbow, and ulnar nerve at the wrist.

a. Musculo-spiral.

b. Ulnar.

(Fig. 309, a). The skin and fasciæ are divided, and the fibres of the supinator longus muscle exposed. This muscle is retracted towards the outer side, when the nerve will become visible lying on the brachialis anticus, a short distance below the point where it has pierced the external inter-muscular septum. The cutaneous portion of the musculo-cutaneous nerve

may be met with, in which case it is drawn aside with a retractor.

The ulnar nerve.—This nerve is a branch of the internal cord of the brachial plexus. In the upper part of the upper arm it lies on the inner side of the brachial artery, but separated from it by the internal vena comes and some connective tissue. The course of the nerve in the upper arm is indicated by drawing a line from the coracoid process to a point half-way between the internal condyle of the humerus and the olecranon. The nerve passes behind the internal condyle and down the forearm to the radial side of the pisiform bone, beyond which point it enters the palm and divides into superficial and deep branches. Its course in the forearm is marked out by a line drawn from a point midway between the internal condyle and the olecranon, to the radial side of the pisiform bone. In this part of its course the nerve lies underneath the flexor carpi ulnaris, until it reaches the region of the wrist, where it becomes more superficial.

1. *To expose the nerve in the middle of the upper arm.*—*Position.*—The patient is placed in the dorsal position, with the arm at right angles to the side, and supinated. The operator stands between the limb and the trunk, and the assistant on the outer side of the limb.

Operation.—An incision 2 in. in length is made in the middle third of the arm, parallel with the line of the brachial artery, and about half an inch to its inner side (Fig. 310, *a*). The skin, the superficial fascia containing the basilic vein, and the deep fascia are divided, and the nerve exposed as it lies on the inner side of the internal vena comes of the brachial artery.

2. *To expose the nerve at the bend of the elbow.*—*Position.*—The patient is placed in the dorsal position, the affected arm is semiflexed at the elbow, and drawn across the chest so as to fully expose the posterior aspect of the bend of the elbow (Fig. 308, *b*).

Operation.—An incision $1\frac{1}{2}$ in. in length is made over the course of the nerve, the central point being half-way between the internal condyle and the inner margin of the olecranon (Fig. 308, *b*). This incision divides the skin and the superficial and deep fasciæ, and exposes the two heads of origin of the flexor carpi ulnaris muscle. The aponeurosis which connects these two heads is incised, and then the nerve will be found lying in the groove behind the internal condyle and upon the posterior ligament of the elbow-joint. If the incision is deepened too much, the cavity of the elbow-joint will be opened. The ulnar artery is a considerable distance from the nerve in this region.

3. *To expose the nerve in front of the wrist.*—The position of the patient is the same as for exposure of the nerve in the upper arm, the hand being well supinated.

Operation.—An incision $1\frac{1}{2}$ in. in length is made over the line of the nerve, commencing below on the radial side of the pisiform bone, and extending upwards on the radial side of the tendon of the flexor carpi ulnaris (Fig. 309, *b*). The skin and fasciæ are divided, and then the nerve will be visible, having the ulnar artery on its radial side.

The median nerve.—This nerve commences opposite the coracoid process by two heads, one from the inner and one from the outer cord of the brachial plexus, and passes downwards in the upper arm, lying first on the outer side of the brachial artery, then in front of it, and finally on its inner side. At the bend of the elbow it is separated from the artery by the internal vena comes. The nerve next sinks between the two heads of

FIG. 310.

| c. | " | " median nerve at wrist. |

the pronator radii teres, and then runs downwards to the middle of the wrist, beyond which point it enters the palm and divides into its terminal branches.

Operation.—1. *In the upper arm.*—The nerve may be exposed in the upper arm by an incision which is the same as for ligature of the brachial artery (Fig. 275, *b*).

2. *At the bend of the elbow.*—At the bend of the elbow it may be exposed by making an incision, $1\frac{1}{2}$ in. in length, parallel with the long axis of the limb, the centre of the cut corresponding to a point one-third of the distance from the internal to the external condyle of the humerus (Fig. 310, *b*). The skin, superficial and deep fasciæ are divided, care being taken to avoid the superficial veins and the internal cutaneous nerve; the nerve will then be exposed as it lies on the brachialis anticus to the inner side of the brachial artery, but separated from this by the internal vena comes. The deep fascia in this region is strengthened by the bicipital fascia from the biceps.

3. *At the wrist.*—The median nerve may also be exposed in front of the wrist.

An incision $1\frac{1}{2}$ in. in length is made, commencing below opposite the middle of the anterior aspect of the wrist, and extending upwards on the ulnar side of the tendon of the flexor carpi radialis (Fig. 310, c). When the skin and fasciæ and the upper fibres of the anterior annular ligament have been divided, the nerve will appear as a large rounded cord, somewhat pinkish in colour, lying to the ulnar side of the tendon of the flexor carpi radialis and underneath the palmaris longus tendon when this is present. At this point the nerve is usually enlarged and fusiform in shape.

The great sciatic nerve.—This nerve is the main continuation of the sacral plexus. It emerges from the pelvis below the pyriformis muscle, and extends towards the popliteal space, ending by dividing into its two terminal branches, the peroneal and popliteal nerves. The point of division varies: in some

FIG. 311.—Incision for exposure of great sciatic nerve.

cases the nerves are given off separately from the sacral plexus, and in others the division occurs in the upper part of the popliteal space. The nerve lies upon the short external rotator muscles of the thigh, and lower down upon the posterior aspect of the adductor magnus. The gluteus maximus covers the nerve above, and the hamstrings below. It is usually exposed immediately below the lower margin of the gluteus maximus.

Position.—The patient lies on the sound side, with the affected lower extremity slightly flexed at the hip and knee. The surgeon stands opposite the exposed buttock, and the assistant on his left hand.

Operation.—An incision $3\frac{1}{2}$ in. in length is made, commencing above a short distance below the midpoint between the ischial tuberosity and the top of the great trochanter, and extending vertically downwards (Fig. 311); the skin, the super-

ficial fascia in which in the lower part of the incision the small sciatic nerve is contained, and the deep fascia are divided, when in the upper part of the wound the oblique fibres of the lower portion of the gluteus maximus will be exposed. These are retracted upwards, and then the hamstring muscles will be seen on the inner side of the incision. These structures are retracted inwards, and the bottom of the wound examined with the finger. The great sciatic nerve will then be felt as it lies upon the adductor magnus, and can easily be lifted up in the wound and stretched. The nerve is returned, and the external wound closed in the usual manner.

The peroneal nerve.—This nerve runs along the outer margin of the popliteal space on the inner side of the biceps tendon. It next pierces the postero-external intermuscular septum, and lies upon the neck of the fibula, underneath the fibres of the peroneus longus muscle, where it divides into the anterior tibial and musculo-cutaneous nerves. The nerve can be felt as a rounded cord lying upon the neck of the fibula, and also at the inner side of the biceps tendon, especially when the knee is extended.

Position.—The patient lies on the sound side, with the affected limb slightly flexed at the hip and the knee, so that it rests on the sound one. The surgeon stands behind the limb to be operated upon, and his assistant opposite to him.

Operation.—An incision 2 in. in length is made, commencing above at the lower border of the head of the fibula, and extending downwards in the long axis of that bone. This incision divides the skin, superficial fascia, and deep fascia, and exposes the outer surface of the peroneus longus muscle. This muscle is divided for the entire length of the incision, and then the nerve will be exposed as it lies upon the bone. Care must be taken, when dividing the muscle, not to divide the nerve as well.

The anterior tibial nerve.—This can be exposed from the front of the leg by an incision similar to that described for the corresponding artery (p. 419).

The popliteal nerve.—The popliteal nerve can be exposed in the lower part of the popliteal space, through an incision similar to that for ligature of the popliteal artery in this region (p. 414).

The posterior tibial nerve.—This nerve runs down the leg in company with the corresponding artery, and it can be laid bare by operations similar to those described for the artery (p. 416).

The anterior crural nerve.—This nerve passes out from the

pelvis through the muscular space beneath Poupart's ligament, lying upon the ilio-psoas muscle half an inch to the outer side of the common femoral artery, from which it is separated by the ilio-pectineal ligament, and a few fibres of the psoas muscle.

Position.—The patient is placed in the same position as for ligature of the common femoral artery.

FIG. 312.—*a*. Incision to expose anterior crural nerve.

Operation.—An incision 2 in. long is made, half an inch outside the artery, and parallel with it. The incision commences above at Poupart's ligament. The skin, superficial and deep fasciæ are divided, and then the nerve may be found lying upon the ilio-psoas muscle, surrounded by a variable amount of fatty connective tissue. In many cases it is difficult to distinguish the nerve on account of this fat.

CHAPTER XXIV.

OPERATIONS ON TENDONS, MUSCLES, LIGAMENTS, AND APONEUROSES.

THE division of a tendon by a surgical operation is called *tenotomy*; that of a muscle, *myotomy*; of a ligament, *syndesmotomy*; whilst the term *aponeurotomy* has been applied to the division of bands of fascia.

These operations may be performed according to two distinct methods of procedure: in the first, the entire operation is carried out subcutaneously through a small skin incision; and in the second an open wound is made so as to fully expose the structure which it is wished to divide. When an operation is performed according to the first of the above methods, it is said to be done “subcutaneously,” and when done according to the second, “by the open method.”

The subcutaneous method.—The advantages of this operation are—(a) The small wound which is necessary, and the avoidance of a scar; (b) the less risk run of the wound becoming infected with the micro-organisms of suppuration. The disadvantage is, the fact that the surgeon is working somewhat in the dark, on which account important structures in the region of the field of operation may be injured, or the tendon which it is proposed to divide may be missed altogether.

The open method.—When performing an operation by this method, an incision, large enough to fully expose the anatomical structure which it is wished to deal with, is made in the situation required. The advantages of this method of procedure are the free exposure of the tissue which it is intended to operate upon, and the lesser liability to injure the adjacent structures; whilst the disadvantages are the resulting scar and the dangers of sepsis. With the aseptic precautions which ought to be adopted in all surgical operations, the last objection need not be taken into serious consideration. In those cases in which the tendon, muscle, or ligament is deeply placed, or is in close relation with

important anatomical structures, it is advisable to adopt the open method; but in cases in which the tendon is easily defined and separated from its surroundings, the subcutaneous method is preferable, and should be made use of.

Special instruments. — When performing an operation by the subcutaneous method, two special knives called tenotomes are requisite, one having a sharp point and the other a blunt one (Figs. 313 and 314); whilst for the open operation the ordinary instruments for a “cutting operation” are necessary.

Method of operating. — In performing an operation by the subcutaneous method, a point in the course of the tendon is selected which lies, if possible, above or below any synovial sheath, and on the same side of the tendon as the most important anatomical structure which might be exposed to injury, and which may thus be more certainly avoided. The sharp tenotome is then pushed inwards so as to pass behind the structure which it is intended to divide, the tendon being slightly stretched so that its position can be defined. The blade of the tenotome is introduced “on the flat,” *i.e.* with the transverse axis of the blade parallel with the long axis of the tendon, and the tissues are divided sufficiently to allow the blunt instrument to be easily introduced. The sharp tenotome is withdrawn, and the blunt-pointed one passed in through the original

FIG. 313.—Sharp-pointed tenotome.

FIG. 314.—Blunt-pointed tenotome.

skin puncture with the blade “on the flat.” When it has been introduced, the cutting edge is turned towards the tendon, the tendon itself is made tense by the assistant holding the limb,

and the structure is divided with a sawing movement, care being taken not to enlarge the skin puncture. The index finger of the surgeon's left hand is held over the tendon where it is being divided, so that the movements of the instrument can be felt, and cutting through the skin avoided.

In a few cases, such as the division of bands of contracted fascia which lie near the surface of the skin and away from any important structure, the entire operation can be completed with the sharp tenotome, but in nearly all other cases it is much safer to use the blunt-pointed instrument as well.

SPECIAL OPERATIONS.

Tenotomy of the sterno-mastoid.—The sterno-mastoid muscle is attached by two heads of origin, one—tendinous—to the upper part of the sternum, and the other—muscular—to the upper border of the inner third of the clavicle. It is enclosed within a sheath of deep cervical fascia. Along the inner border of the sternal head lies the anterior jugular vein, and in relation with the clavicular head lies the external jugular vein. The carotid sheath with its contents is situated directly behind the muscle, but portions of the sterno-hyoid and sterno-thyroid muscles intervene. The two heads of the muscle are divided separately, through different incisions.

Position.—The patient is placed in the dorsal position, with a pillow underneath the shoulders, and with the head projecting slightly beyond the top of the table. The head is rotated towards the unaffected side by an assistant, who holds it in this position so as to keep the muscle on the stretch.

The surgeon stands upon the affected side of the patient, and the assistant on the opposite side.

Operation.—An incision with the point of a sharp tenotome is made at the inner border of the sternal head of the muscle, about one-third of an inch above the sternum, and deepened until the deep fascia has been divided and the tendon of the muscle exposed. The sharp instrument is then withdrawn, and the blunt one introduced. The tenotome is now carefully pushed behind the tendon, with the blade "on the flat," until it can be felt in the interval between the two heads of the muscle. The cutting edge of the knife is now turned towards the skin, and the muscle divided with a slight sawing movement. The forefinger, during the division of the tendon, is kept over the skin in front of the field of operation. The clavicular head of the muscle is next divided in a similar

manner, by entering the tenotome at the outer border of the muscle, about one-third of an inch above the clavicle. Care must be taken in this part of the operation not to injure the external jugular vein.

On account of the close proximity of important structures, some surgeons advise that the sterno-mastoid should only be divided through an open incision.

In practice it will be found more convenient to divide the sternal head by the subcutaneous method, and the clavicular head by the open method.

The adductor longus.—This tendon may be divided a short distance below its attachment to the body of the os pubis.

Position.—The lower extremity is placed in a position of semiflexion, abduction, and external rotation.

The surgeon stands on the outer side of the limb to be operated upon, and the assistant on the opposite side.

Operation.—The outer margin of the tendon is defined about half an inch below the pubic spine, and the sharp tenotome introduced. When an aperture has been made, the blunt instrument is introduced, and the tendon divided by cutting towards the surface. A small branch of the superficial pudic artery may be injured, but usually the tendon is divided below this vessel.

The biceps femoris.—The tendon of the biceps femoris is usually divided a short distance above its insertion into the head of the fibula.

Position.—The patient lies as far as possible on the sound side.

The operator stands behind the patient and the assistant on the other side.

Operation.—The position of the tendon is defined about an inch above the head of the fibula, along the outer border of the popliteal space. A point is selected on the tibial margin of the tendon, and with the thumb of the surgeon's left hand the peroneal nerve is separated from the tendon. The sharp tenotome is then taken, and a small puncture made which extends down to the surface of the tendon. The sharp tenotome is withdrawn, and the blunt one introduced. The handle of this instrument is depressed, and the blade insinuated underneath the tendon, which is then divided by cutting outwards with a sawing movement. It is possible to mistake the ilio-tibial band of the fascia lata for the tendon of the biceps muscle.

In order to more certainly avoid the peroneal nerve, it is best to conduct this operation through an incision parallel to the biceps tendon, by the open method.

The semitendinosus and semimembranosus.—The tendons of these muscles may be divided by a procedure similar to that for the division of the biceps. They lie on the inner side of the popliteal space, and they are divided about an inch above the knee for the semitendinosus, and half an inch for the semimembranosus. The tenotome is entered on the fibular side of the tendons. The popliteal nerve lies near the middle of the popliteal space, and is not likely to be injured.

The tendo Achillis.—The tendo Achillis is the tendon of insertion of the soleus and gastrocnemius muscles, and is attached to the prominence of the os calcis. The narrowest portion of the tendon is situated about 1 in. above its insertion, and it is at this point that the tendon is divided.

Position.—The patient is placed in the dorsal position, but lying somewhat on the side of the affected limb; the leg is allowed to project a short distance beyond the end of the table, and is turned on its outer side so as to fully expose its tibial aspect.

The surgeon stands on the outer side of the foot, and the assistant opposite to him, holding the foot with one hand and the leg with the other.

Operation.—The tendon is slightly stretched, so as to render its position definite, and the sharp tenotome entered at its tibial margin about 1 in. above the heel. The tenotome is made to pass in front of the tendon until it can be felt at the fibular margin. The sharp instrument is withdrawn and the blunt one introduced. The cutting edge is turned towards the tendon, and the foot fully flexed by the assistant, so as to make the tendon quite tense. The tendo Achillis is now divided with a slight sawing movement, the forefinger of the surgeon's left hand being held over the portion of the tendon which is being divided, so as to guard against injury of the overlying skin. Care must be taken to divide the entire tendon. It sometimes happens that the tenotome is passed through the tendon itself, if the convexity forwards of the tendon is not remembered, in which case only the superficial part will be divided.

The tendon of the tibialis anticus.—This tendon lies in the innermost compartment of the anterior annular ligament of the ankle-joint, and it has a separate synovial sheath, which extends upwards about 1 in. or $1\frac{1}{2}$ in. above the ankle, and downwards to within 1 in. of the insertion of the muscle into the tibial side of the internal cuneiform and the base of the metatarsal bone of the great toe.

The tendon is usually divided immediately below the synovial

sheath, that is to say, not quite 1 in. above the insertion, and as it lies in relation with the scaphoid. It is separated from the dorsalis pedis vessels by the extensor proprius hallucis.

Position.—The surgeon stands on the outer side of the leg, which should project over the end of the table, the patient lying in the dorsal position. The assistant stands opposite, holding the foot with one hand and the leg with the other. The foot is abducted and extended, by which means the tendon is made tense, and can easily be defined.

Operation.—The tenotome is entered on the fibular side of the tendon, a short distance in front of the prominence of the scaphoid, and is made to pass underneath the tendon until it can be felt at the tibial margin. The tendon should be somewhat relaxed as the tenotome is being introduced. When a way has been made for the blunt instrument with the sharp one, the latter is withdrawn and the former introduced. The cutting edge is turned towards the tendon, and the tendon again made tense, and divided from behind forwards, the surgeon's left forefinger being placed over the skin so as to act as a guide and prevent his cutting through to the surface.

The tendon of the tibialis posticus.—The tendon of the tibialis posticus occupies the internal compartment of the internal annular ligament of the ankle-joint, and is surrounded by a synovial sheath, which extends upwards for about 1 in. above the tip of the internal malleolus. The tendon of the flexor longus digitorum lies in the next sheath, and separates it from the posterior tibial vessels and nerve.

The tendon is usually divided above the synovial sheath, that is, immediately above the base of the malleolus.

Position.—The patient lies in the dorsal position, with the foot held in a position of slight flexion and abduction, and placed upon the fibular side. The surgeon stands on the outer side of the limb, and the assistant, opposite to him, holds the foot in the required position.

Operation.—The posterior border of the internal malleolus is defined and traced upwards until the part of the shaft above the base of the malleolus is reached. This point in the adult is about $1\frac{1}{2}$ in. above the tip of the malleolus, but in young children it is not more than two-thirds of an inch above. When this point has been defined and the tendon felt, the foot is relaxed and the postero-internal border of the bone fixed with the thumb of the surgeon's left hand. The sharp tenotome is now passed inwards in a vertical direction between the tendon and the bone, and moved laterally so as to make a passage for the

blunt instrument. When this has been done, the blunt tenotome is introduced and the cutting edge turned towards the tendon. The tendon is next made tense by again flexing and abducting the foot, and divided in the usual manner. As the last fibres of the tendon are being divided, the foot is again relaxed by the assistant. If the tenotome is passed too deeply, it occasionally happens that the posterior tibial vessels are injured. If this accident should occur, pressure by means of a pad and bandage must be applied at once. In many cases the tendon of the flexor longus digitorum is divided as well.

The tendons of the peronei.—These tendons lie behind the external malleolus in a common groove, the peroneus longus being superficial and the peroneus brevis deep. They are surrounded in this position by a common synovial sheath, which extends upwards for about 1 in. above the base of the malleolus, and subdivides below into two portions, one for each tendon. The tendons are generally divided in the leg a short distance above the termination of the synovial sheath.

Position.—The patient lies on the sound side, with a sandbag placed underneath the lower third of the leg, and with the foot flexed and adducted. The foot rests on its tibial aspect, the fibular surface being in front of the surgeon. The operator stands behind the affected limb, and the assistant, opposite to him, holds the leg steady in the position mentioned.

Operation.—The posterior border of the external malleolus is traced upwards, and a point selected about $1\frac{1}{2}$ in. above the apex of the malleolus. The sharp tenotome is entered at this spot (the tendons being relaxed at the time), and made to pass inwards between the bone and the tendons. The sharp instrument is withdrawn, the blunt one introduced, and its edge turned away from the bone. The tendons are then rendered tense, and divided in the usual manner. The short saphenous nerve and vein are behind the tendons at the level of the point of division, and do not run any risk of being wounded if the above directions are adhered to.

The tendon of the extensor proprius hallucis.—This tendon lies in a separate compartment underneath the anterior annular ligament of the ankle-joint, surrounded by a distinct synovial sheath. The tendon is situated on the fibular side of the tibialis anticus and between it and the dorsal vessels of the foot. The tendon is divided a short distance below the bend of the ankle.

Position.—The patient lies in the dorsal position, with the affected foot projecting beyond the end of the table, where it is

held in an extended position by the hands of an assistant. The operator stands on the outer side of the foot.

Operation.—A point on the fibular side of the tendon is selected about 1 in. below the bend of the ankle, and with the thumb of the surgeon's left hand the dorsal vessels are held well away from the seat of operation. The tenotome is entered on the fibular side of the tendon, and passed inwards until its point can be felt between it and the *tibialis anticus*. The sharp tenotome is then replaced by the blunt one, and the tendon divided in the usual manner. There is no risk of injuring the dorsal vessels if they are protected with the thumb of the left hand.

The tendons of the *extensor longus digitorum* and *peroneus tertius*.—These tendons lie in the same compartment of the anterior annular ligament of the ankle-joint, and are surrounded by the same synovial sheath. The *dorsalis pedis* vessels lie on the tibial side. The tendons are divided 1 in. below the ankle-joint.

Position.—The position of patient and assistant are the same as for the preceding operation, but the surgeon stands on the tibial side of the affected limb.

Operation.—The dorsal vessels are protected with the surgeon's left thumb, and the tenotome entered on the tibial side of the tendons. The tendons are divided by cutting outwards towards the skin.

Division of the plantar fascia.—The plantar fascia is divided in certain cases of talipes, and in most instances it is the central portion which requires attention. This part is attached posteriorly to the internal tubercle of the calcaneum, while anteriorly it divides into five bands which pass to the toes. The fascia is usually divided in several places, the first point of division being a short distance in front of the calcaneum.

Position.—The patient is placed in the dorsal position, with the affected limb raised by placing a pillow or sandbag underneath the leg. The surgeon stands on the outer side of the foot and the assistant opposite him. The foot is grasped by the hands of the assistant and flexed at the ankle, the toes being extended so as to make tense the bands of fascia.

Operation.—A fine sharp-pointed tenotome is taken, and the blade passed between the skin and the contracted band of fascia, from whichever side is the more convenient. The cutting edge is turned towards the sole, and the fascia divided by cutting inwards. It is better to make several punctures and divisions of the fascia than to completely divide it through one incision.

Division of the palmar fascia (operation for Dupuytren's contraction).—Dupuytren's contraction consists in a pathological shortening of the bands of the palmar fascia passing to the fingers. For the relief of this condition, two operations, the *subcutaneous* and the *open*, are practised.

Subcutaneous operation.—The affected hand is placed in a position of supination. A fine sharp-pointed tenotome is used, and passed into the tissues between the skin and the contracted band of fascia. This is then divided by cutting away from the surface. It is necessary to divide the fascia in several places, and when the division is being made the fingers should be stretched by an assistant, so as to render the bands tense and distinct. Care must be taken not to allow the point of the tenotome to pass too near the margin of the finger, otherwise the digital vessels and nerves may be damaged. The points of puncture should be selected where the bands of fascia are not adherent to the overlying skin.

Open operation.—The hand is held in the same position as for the subcutaneous operation. A vertical incision is made through the skin and superficial fascia of the affected finger and the adjacent portion of the palm. This incision commences in the palm above the commencement of the contraction, and extends along the middle line of the affected finger to a point well beyond the contraction. The incision is deepened until the deep fascia is reached, and then the skin and superficial fascia are dissected up on each side. By this means the contracted bands of the palmar fascia are exposed. These are divided transversely, and are then, as far as possible, removed. It is requisite in this operation to have the tissues of the hand rendered bloodless by the application of an Esmarch's bandage. When the contracted bands have been separated, divided, and removed, the bandage is taken off, and if any bleeding points can be seen they are ligatured. The margins of the skin wound are next brought into exact apposition, and united with fine sutures of horse-hair or salmon-gut. The limb is put up on a splint with the fingers fully extended.

When a case of Dupuytren's contraction is treated by the subcutaneous method, it is necessary to apply splints very carefully, and to see that they are worn for some considerable time, so as to prevent the return of the original condition. The open operation is a more severe one, but if precautions are adopted to avoid the occurrence of septic processes, the duration of treatment is much shorter than with the subcutaneous method, and a recurrence is not so likely to take place.

Division of the astragalo-scaploid ligaments (syndesmotomy).—In this operation the ligaments which form the connection between the astragalus and scaphoid are divided by a subcutaneous operation.

Position.—The patient lies in the dorsal position, with the foot placed upon its outer side.

The surgeon stands on the tibial side of the foot, with an assistant opposite to him, who holds the foot firmly in position.

Operation.—A point is taken a short distance below and in front of the apex of the internal malleolus, and just behind and above the tuberosity of the scaphoid. The sharp-pointed tenotome is introduced at this point, and pushed forwards and inwards until a point on the tibial side of the dorsal vessels is reached. It is then withdrawn, and a special form of curved tenotome passed in along the tract which has been made. The

FIG. 315.—Suture of divided tendons.

a. Ends pared and sutures inserted.
b. Sutures tied.

cutting edge of this instrument is turned towards the bones, the foot is fully extended so as to render the ligaments and tendons tense, and then the knife is withdrawn; as this is being done it is made to cut all the structures down to the bone, the tendon of the tibialis posticus being divided just before the point emerges. The foot is then put up in the corrected position.

This operation has been done in a considerable number of cases of congenital talipes varus, and with a fair amount of success.

Suture of divided tendons.—Tendons frequently require to be joined together when they have been partially or completely severed as the result of injury, as after incised wounds in the region of the wrist.

Operation.—The first part of the operation is the free exposure of the divided ends of the tendon. In order to do this,

it is often necessary to enlarge the wound in a proximal direction, since the muscles may contract and draw the proximal end of the tendon up within the tendon sheath.

The severed ends of the tendon having been exposed, the free extremities, if lacerated, are trimmed with scissors, and brought into apposition.

With a fine needle the tendon is transfixcd, as in Fig. 315, and sutures inserted. When all the necessary sutures have been introduced, each one is tied and the ends cut short. The external wound is then closed in the usual manner.

The limb is placed on a suitable splint, and maintained in a quiescent state until the approximated ends have had time to unite.

When it is found impossible to find the proximal end of the

FIG. 316.—Lengthening of tendons. By a vertical incision.

a. Line of incision in tendon.

b. The two portions separated for a distance and sutures inserted.

divided tendon, or to bring the two extremities into apposition, the distal end may be implanted on the lateral aspect of one of the adjacent tendons, preferably one of a muscle which has an action similar to the one divided, or an attempt may be made to lengthen the tendon, as in the next operation.

When implantation is attempted, the lateral aspect of the tendon on which the severed extremity is about to be fixed is refreshed before the insertion of the sutures. This lateral implantation has been adopted in the case of paralysis of the gastrocnemius and soleus, the tendon of the peroneus longus being divided and joined on to the tendo Achillis.

Lengthening tendons.—Lengthening of one or more tendons may be requisite under the following conditions :—

(*a*) In some cases of severed tendons, in which the cut ends cannot be readily approximated

(b) When a portion of tendon is removed, as in the extirpation of a malignant growth, and the ends cannot be brought together.

(c) In some cases of congenitally contracted tendons, where it is not wished to divide the tendon completely across.

(d) After sloughing of a portion of a tendon.

Operation.—Two methods of lengthening a tendon are practised—

1. *By a vertical incision.*—The tendon which it is wished to lengthen having been exposed, an incision is made in its long axis, as in Fig. 316, *a*. The two portions are separated as in Fig. 316, *b*, and fixed together by the insertion of a number of fine sutures of silk, which transfix both parts of the tendon. The severed ends of the tendon thus lengthened are united, and

FIG. 317.—Lengthening of tendons. By alternate transverse incisions.

a. Position of alternate incisions.

b. Appearance of a tendon when lengthened, and the margins of the incisions have separated in a V-shaped manner.

then it is replaced in its normal position, the fascia sewn over it, and the external wound closed. A splint is applied so as to prevent movement of the affected part of the limb, and kept in position until the parts have become joined. Two or three weeks are usually sufficient for the purpose.

2. *By alternate transverse incisions.*—The tendon having been exposed, a number of transverse incisions placed alternately on each side of the tendon are made, after the method illustrated in Fig. 317, *a*. Each incision ought not to divide more than one-half the thickness of the tendon.

When the incisions have been made and the tendon stretched, the latter has the appearance shown in Fig. 317, *b*. The limb is fixed in the rectified position by a splint, as in the preceding operation.

CHAPTER XXV.

OPERATIONS ON THE BONES.

OSTEOTOMY.

OPERATIONS FOR FRACTURE.

EXCISION OF BONES.

Osteotomy.—By the term osteotomy is understood complete division of a bone in its continuity. Two forms of this operation are practised—

(a) *Linear osteotomy.*—In this procedure a bone is divided transversely, usually through a small skin incision, the operation being more or less of the nature of a subcutaneous one.

FIG. 318.—Chisel. Cutting edge.

(b) *Wedge-shaped or cuneiform osteotomy.*—In this operation, in addition to the division of the bone, a wedge-shaped portion is removed.

FIG. 319.—Osteotome. Cutting edge.

The operation of osteotomy is required in the majority of instances for the rectification of a congenital or acquired malformation of one or more bones, or for ankylosis of a joint in a bad position. Usually this condition is the result of rickets, or of union of a bone in a faulty position after it has been fractured.

Special instruments.—Long-bladed narrow scalpel, chisel, osteotomes, wooden mallet, suitable splints.

In certain cases, pressure forceps and retractors may be required, and occasionally some form of saw.

In linear or transverse osteotomies an osteotome is used for division of the bone; in wedge-shaped osteotomy a chisel will be found more convenient for the purpose. Figs. 318 and 319 show the shape of the cutting edge of a chisel and osteotome respectively.

Osteotomy of the lower extremity of the femur.—

Indications.—(a) Those forms of genu valgum dependent upon malformation of the femur, which are not readily amenable to rectification by instruments, splints, or other means.

(b) Some cases of genu varum associated with malformation of the lower end of the femur.

(c) Occasional cases of malformation of the lower end of the femur, resulting from injury or after fractures.

Different forms of operation.

—Several different methods of operation are practised for the rectification of the above forms of malformation of the femur. The three most important ones are—

(a) Transverse division of the femur just above the condyles (Macewen's supracondylar operation), through an incision on the inner side.

(b) Transverse division of the femur a short distance above the

condyles, through an incision on the outer side.

(c) Detachment of the internal condyle (Ogston's or Reeves' operation).

Supracondylar osteotomy of the femur (Macewen's operation).—*Position.*—The patient is placed in the dorsal position, with the knee somewhat flexed, and the lower extremity rotated outwards so as to lie upon its outer side. A moderate-sized sandbag is placed beneath the knee of the affected side, so as to support it.

It is advisable in this operation to remove all mattresses and pillows from between the patient and the operating table.

The surgeon stands on the opposite side of the patient to the affected limb, and his assistant opposite to him.

FIG. 320.—Supracondylar osteotomy of femur.—MACEWEN.

a. Position of skin incision.

b. Adductor tubercle of femur.

Operation.—A point is taken half an inch above and anterior to the adductor tubercle of the femur, which point indicates the line of junction between the epiphysis and shaft. A long-bladed scalpel is pushed inwards to the bone, the incision being parallel to the long axis of the limb. All the soft tissues, including the periosteum, are divided down to

FIG. 321.—Macewen's osteotomes.

FIG. 322.—Femur, showing parts derived from primary and secondary centres.

the bone for about three-quarters of an inch. The osteotome is now passed downwards to the bottom of the wound along the

blade of the scalpel, which serves as a director. The scalpel is then withdrawn, and the osteotome is turned until its blade

- a. Shaft.
- b. Lower epiphysis.
- c. Head.
- d. Great trochanter.
- e. Small trochanter.

is at right angles to the shaft of the femur. A series of short sharp strokes is given with the mallet, so as to drive the cutting part of the osteotome through the femur. The osteotome should be so manipulated that the postero-internal margin of the femur is first divided, and the section then continued forwards and outwards in such a manner that the posterior fourth of the femur is left undivided. The section of the femur should be made at right angles to its shaft; if this is not done, the cut may extend in young people into the epiphyseal cartilage, a complication which ought to be avoided.

After each blow with the mallet the osteotome should be moved to and fro, so as to prevent its becoming impacted in

the bone, but any upward and downward movement (with reference to the long axis of the limb) must be avoided. The latter part of the section of the bone may be facilitated by using a smaller osteotome, but this is not usually requisite. It is best to grasp the osteotome so that the ulnar aspect of the hand rests on the patient's thigh, so as better to control the movements of the osteotome.

When the section with the osteotome has extended to the outer part of the bone, the instrument is removed. The thigh is then grasped with the right hand, a short distance above the line of section,

FIG. 323.—Osteotomy of femur. Transverse division through an external incision.

a. Position of incision.

b. Prominence of external condyle.

and the leg with the left hand, and by forcible flexion the remaining part of the bone is fractured.

The limb is brought into a straight position; one or two points of suture are used to close the skin incision, and aseptic dressings applied.

The limb is fixed in position by the application of a long outside splint, and short back and side splints. After the expiration of from four days to a week the splints may be removed, the stitches taken out, and the limb encased in plaster.

After-treatment.—The plaster case should be kept on for about six weeks from the time of operation. It is then re-

moved, and if union is found to be firm, the patient is allowed to get about on crutches.

Transverse division of the femur above the condyles, through an external incision.—In this operation the skin incision is usually made at a somewhat higher level than in the previous operation.

Position.—The patient is placed in the dorsal position; the affected limb is slightly flexed and rotated inwards, a sandbag being placed at its internal aspect to support it.

The surgeon stands at the outer side of the affected limb, and the assistant opposite him.

Operation.—An incision is made, about three-quarters of an inch in length, 3 in. above the external condyle of the femur. This incision divides the skin, fasciæ, vastus externus muscle, and periosteum. Either a saw or an osteotome may be used for the division of the bone.

In the former case, an osteotomy saw, of the shape shown in Fig. 324, is passed along the knife down to the bone; the knife is withdrawn, and the bone divided for two-thirds of its extent by a series of short to-and-fro movements. The saw is now withdrawn, and the remaining part of the bone fractured, as in Macewen's operation.

If an osteotome is used, the procedure is similar to that described in the previous operation, with the exception that the section is commenced from the outer side.

When the section of the bone has been completed, the wound in the soft tissues is washed out so as to remove all bone dust and other foreign material, and the skin incision closed with sutures. Splints are afterwards applied, as in the previous case.

Detachment of the internal condyle.—*Position.*—The positions of the patient, operator, and assistant are similar to those for Macewen's operation.

Operation.—A point is taken about 2 in. above and a little anterior to the adductor tubercle of the femur. A long-bladed knife is pushed through the soft tissues of the thigh at this point in a downward and outward direction, until the anterior inter-

FIG. 324.—Osteotomy saw.—ADAMS.

condylar notch of the femur is reached. Portions of the vastus internus and crureus and synovial membrane are divided. The skin incision may be slightly enlarged as the knife is withdrawn. Before doing this, however, the blade of an osteotomy saw is passed along the knife into the notch. The cutting part of the

FIG. 325.—Osteotomy of femur. Detachment of internal condyle.—OGSTON.

a. Line of division of bone.

FIG. 326.—Internal condyle detached.—OGSTON.

a. Internal condyle.

saw is turned towards the popliteal space, and the bone sawn through for the anterior three-quarters of its thickness. The saw is removed, and the leg bent forcibly inwards, by which means the internal condyle is completely detached and caused to slide upwards on the inner side of the femur.

The external incision is closed, and dressings and splints are now applied.

An osteotome may be used in place of the saw, if the surgeon prefers it.

The disadvantages of the above operation are—The knee-joint is opened and the position of its internal ligaments seriously changed. Stiffness is liable to follow the operation, owing to the formation of adhesions, and if strict aseptic precautions are not observed septic arthritis may follow. Probably the only condition in which the operation may with advantage be performed is in cases of very great enlargement of the internal condyle which cannot be satisfactorily treated by transverse osteotomy of the bone.

Osteotomy of the upper extremity of the femur.—Division of the upper portion of the femur may be effected either through the neck of the bone or through the shaft below the trochanters. The latter operation is the more easy to perform, and gives better results. Moreover, in many cases which require this procedure, the neck of the bone has been partially or completely destroyed as a result of disease.

FIG. 327. — Osteotomy of femur. Subtrochanteric operation.

a. Position of skin incision.

Indications.—Ankylosis of the hip-joint, with the limb fixed in a bad position. This may be due to previous tuberculous disease of the hip-joint; to suppurative arthritis of the hip-joint, such as occurs in pyæmia; or to ankylosis after gonorrhœal arthritis or rheumatoid affections.

Position.—The patient lies somewhat on the sound side, with the outer aspect of the affected hip well exposed. The operator stands on the affected side of the patient, and the assistant directly opposite to him.

Operation.—A point is selected on the outer side of the limb a short distance below and anterior to the great trochanter of the femur (Fig. 327). A long-bladed scalpel is pushed inwards down to the bone at this point, with its blade parallel to the long axis of the limb, and the skin, fasciæ, muscle, and periosteum are divided. The incision should be about three-quarters of an inch in length. The osteotomy saw is pushed along the blade of the knife down to the bone, the latter instrument being

now withdrawn. With the saw the femur is divided for the anterior three-fourths of its thickness. The saw is then withdrawn, and the thigh is forcibly straightened, by which means the remaining part of the bone is fractured. The incision in the soft tissues is closed with sutures, an aseptic dressing is applied, and the limb fixed in the rectified position by means of a long outside splint.

After-treatment.—The limb should be kept in this position until firm union has been obtained, usually for about six weeks.

It is not advisable to attempt to create a false joint at the line of section, since very poor results have usually followed such attempts.

Some surgeons, especially Adams, have advocated division of the neck of the femur within the capsule. This is effected through an incision above the great trochanter. In my opinion, however, this operation does not give such good results as the one which has been above described.

Osteotomy of the tibia.—This operation may consist in either simple transverse section of the tibia, or section combined with removal of a wedge-shaped portion.

Indications.—Malformed curved tibiæ, due to rickets, syphilis, osteomalacia, or the result of injury, and certain cases of ankylosis of the knee-joint in which the limb is in a bad position.

Position.—The patient is placed in the dorsal position, with the affected limb lying upon its outer side, a sandbag being placed beneath it. The surgeon stands on the outer side of the limb, and the assistant opposite him.

Operation.—(a) *Simple transverse section of the tibia.*—A vertical incision 1 in. in length is made over the most prominent part of the deformed portion of the bone. In making this incision, it is advisable to pull the skin well inwards with the left hand, so that, after the section of the bone has been made, the superficial opening may be a short distance from the line of fracture. The soft parts—skin, fasciæ, and periosteum—are divided down to the bone. The osteotome is then introduced, its cutting part turned at right angles to the long axis of the tibia, and that bone divided with the aid of the mallet, as in osteotomy of the femur. An osteotomy saw may be used in place of the osteotome, if preferred.

The tibia having been almost completely divided in this manner, the limb is grasped above and below the plane of section and forcibly straightened. In doing this the fibula is fractured at the same time that the undivided portion of the tibia is broken across.

The wound is sponged dry, closed with a few points of suture, and aseptic dressings applied. The limb is fixed in the rectified position by the application of back and side splints.

After-treatment.—Careful attention should be paid to the position of the limb, so as to avoid any displacement. After from five to seven days the splints are taken off, the stitches removed, and the limb put in a plaster or silicate case.

(b) *Transverse osteotomy, with removal of a wedge-shaped portion of bone.*—The first stage of this operation is similar to the above, with the exception that the incision is made a little longer and the periosteum is detached from the tibia for a short distance, usually 1 in. or $1\frac{1}{2}$ in. The soft parts, including the periosteum, are held aside with retractors, and a wedge-shaped portion of the tibia, the base of the wedge being anterior, removed with a chisel (Fig. 328). Care must be taken to completely divide the bone posteriorly, and if there is any difficulty in getting the limb straight the periosteum on the posterior part of the tibia should be divided also. The wedge-shaped piece of bone having been removed, the limb is forcibly straightened and put up in splints, as in the preceding case.

In certain cases of bony ankylosis of the knee-joint, with the limb in a faulty position, it may be necessary, in order to rectify the deformity, either to divide, or to divide and remove a wedge-shaped portion from the upper extremity of the tibia.

This operation is similar to the preceding one, with the exception that the skin incision is made over the upper fourth of the tibia.

Operations for fracture. — *Indications.* — Those cases of ununited fracture of bone,—usually the femur, tibia, humerus, radius and ulna, patella, or olecranon, which do not unite after treatment by splints,—some cases of recent fracture, particularly of the patella and olecranon, and also those cases of recent fracture of the long bones in which extensive displacement has occurred, and, after reduction, the fragments cannot be kept in apposition or good position.

FIG. 328.—Osteotomy of tibia. Removal of wedge-shaped portion.

a. Portion of bone to be removed.

Special instruments.—Periosteal elevators, chisel, mallet, osteotomy saw, bradawl, and suitable splints.

Ununited fracture of the femur.—*Preliminary preparations.*—In those cases of ununited fracture of the femur in which there is considerable shortening owing to malposition of the fragments of bone, it is advisable to keep the patient in bed for a few days previous to the operation, and to apply extension to the affected limb. By this means the deformity will be lessened, the muscles somewhat lengthened, and it will be possible to fashion a suitable splint for application after the performance of the operation.

Position.—The patient is placed in the dorsal position, with the thigh of the affected limb resting upon a sandbag. The surgeon stands upon the affected side of the patient and the assistant upon the sound side.

Operation.—The position of the fracture is first defined. A vertical incision 4 or 5 in. in length is made on the outer side of the limb, the centre of the incision being opposite the seat of fracture. The soft tissues of the thigh—skin, fasciæ, muscle, and periosteum—are divided down to the bone for the entire length of the incision. Next, the free extremities of the fractured ends of the bone are laid bare by turning aside the soft tissues surrounding them, and at the same time the periosteum is detached from the femur above and below the fracture for a distance of about half an inch. The ends of the bone having been freed in this manner, the limb is bent until one of them projects into the wound. The soft parts are protected with flat retractors, and then with chisel and mallet a portion of the end of the bone, about a quarter of an inch in thickness, is removed. The other extremity is now brought into the wound and treated in a similar manner. In making the section of the bone, care must be taken so to fashion the two free extremities that they may fit one another when brought together. In order to do this satisfactorily, it is better to make one end somewhat convex and the other somewhat grooved or concave. The ends of the bone, when properly prepared, are brought into apposition, and the external wound closed. Splints are then applied, so as to fix the limb immovably in the position in which it has been placed.

Some surgeons have advised that the two ends of the bone should be fixed together by sutures of strong silver wire, metal screws, or ivory pegs. In my opinion, however, these methods of fixation of the bone are of little advantage, since, if care be taken to make a free exposure of the fractured ends, to fashion

the two extremities so that they fit together, and to apply suitable splints, few, if any, failures will be met with.

When, however, the line of fracture is very oblique, or the two ends cannot be made to remain in apposition, the two fragments should be joined together by one or two stout silver wire sutures.

Senn has suggested that when the two extremities of the bone have been freed, and the thickened periosteum removed, a bone "ferrule" should be used to hold them in apposition. A sufficient number of cases treated in this manner have not, however, as yet been recorded to justify its inclusion as a recognised surgical operation.

Ununited fractures of the tibia and fibula, radius and ulna, and humerus, are treated in a manner exactly similar to the above.

Fracture of the patella.—*Operation.*—A vertical incision is made

over the middle of the anterior aspect of the limb, commencing 1 in. above the lower border of the upper fragment, and terminating 1 in. below the upper border of the lower fragment. The soft parts are divided down to the anterior surface of the bone, and dissected outwards for a short distance, and held aside by retractors. In this way the anterior surface of the two fragments of the patella is exposed, and if the fracture is not a recent one, the intervening fibrous tissue which holds them together. All bleeding is now arrested, and the fibrous tissue which lies between the two fragments is removed. When the knee-joint has been thus laid open, all fibrin and blood clot is removed from its interior and also from the fractured surfaces of bone. Next, except in recent cases, a thin layer of bone is taken away

from the fractured surfaces with the chisel and mallet. This proceeding is only necessary in patients in whom the fracture has occurred some time previously. The fragments

FIG. 329. — Operation for fracture of patella.

a. Position of external incision.

FIG. 330. — Section of patella, showing method of inserting sutures.

are now pierced with a bradawl, in the manner shown in Fig. 330. It is best to pierce each fragment about half an inch from the middle line on each side. A suture of strong silver wire, about one-twelfth of an inch in thickness, is passed through the

FIG. 331.—Section of bone, showing sutures inserted and fixed.

perforation in each half of the bone, and by tightening and twisting this the prepared surfaces of the two fragments are fixed in apposition, all blood and débris having been previously sponged away. The ends of the suture are cut short and hammered into the upper margin of the bone. In the majority of instances it is advisable to have two sutures, each being inserted half an inch towards the corresponding side of the middle line. The external wound is closed by the insertion of silkworm-gut sutures, and the limb is fixed in the fully extended position by the application of splints. Passive movements of the knee-joint should be commenced at the end of two weeks from the time of operation. Some surgeons advise

that when union is complete, the wire suture should be removed through an incision made over it. This is not usually necessary.

Fracture of the olecranon.—In fracture of the olecranon process of the ulna, an operation similar to the one described for fracture of the patella, may be made use of.

A vertical incision is made in the long axis of the limb, over the posterior aspect of the elbow. The fragments are defined, all blood clot and fibrin removed from the interior of the joint, the fractured surfaces separated from all fibrous tissue and synovial membrane, and freshened, if necessary, in old cases by the removal of a plate of bone with the chisel, and then fixed in apposition by the insertion of wire sutures. The limb is put up on an anterior splint, and maintained in position of almost complete extension.

FIG. 332.—Position of sutures on anterior aspect of patella.

In many cases of widely separated ununited fractures of the patella and olecranon, difficulty is experienced in bringing the surfaces of the fractured portions of the bones together. When

this happens, the fibres of the rectus femoris muscle might be divided in the former case, and those of the triceps humeri in the latter, just above their insertion.

Excision of bones.—An excision of a bone may be either partial or complete. In the former case only a part of the bone, either of the shaft or an extremity, is taken away; in the latter, the entire bone, including its articular surfaces, is removed. Sometimes a bone is only partially detached, and turned aside, and afterwards replaced and fixed in its original position. This is called “temporary” or osteoplastic resection, and may be performed, for example, in the case of the upper jaw, to allow of the removal of a naso-pharyngeal polypus. It is also employed in connection with the cranial vault, in order to obtain a free exposure of portions of the brain or membranes.

Special instruments.—Resection knife, bone forceps, lion forceps, periosteal elevator, sequestrum forceps, and saw.

Indications.—(a) New growths of bone, especially sarcomata.

(b) Localised inflammatory affections associated with the formation of sequestra or abscesses.

(c) Some forms of malformation, either congenital or acquired, such as inveterate club-foot.

(d) As a temporary measure in some forms of intracranial growth, and in the removal of naso-pharyngeal polypi.

Temporary excision of a portion of the bony wall of the cranium is described on p. 332.

Excision of the upper jaw.—This may be (1) complete, (2) partial, or (3) temporary.

Preliminary laryngotomy is adopted by some surgeons, but, in my opinion, is not usually necessary.

1. *Complete excision of the upper jaw.*—This operation is performed for malignant growths of the upper jaw, sarcomatous or carcinomatous, which have not extended beyond this structure into the adjacent tissues.

Special instruments.—In addition to the ordinary instruments for the excision of a bone, a gag and a pair of upper-incisor dental forceps are required. A key-hole saw and a Hey's or other form of small saw are also required.

Position.—The patient is placed in the dorsal position, with the head supported by a pillow, and near the right margin of the operating table. The surgeon stands on the right side of the patient (both for right and left upper jaws), and the assistant stands on the left, directly opposite to him.

Operation.—The operation for the removal of the upper jaw may conveniently be divided into the following stages:—(a)

External incision, and dissection back of cheek-flap; (*b*) division of bony connections, and removal of incisor tooth; (*c*) division of soft palate, and removal of jaw.

(*a*) *External incision, and dissection back of cheek-flap.*—An incision is made, commencing below and a little internal to the internal canthus of the eye of the affected side, extending downwards along the lateral aspect of the nose as far as the ala, then horizontally inwards to the middle line opposite the septum, and finally vertically downwards through the upper lip into the mouth (Fig. 333). From the same starting-point a second incision is carried outwards, parallel with the inferior margin of the orbit, as far as the prominence of the malar bone. Both

FIG. 333.—Excision of upper jaw.
a. Position of external incision.

parts of the incision divide skin, fasciæ, and muscle, and a flap is dissected back including all the soft tissues of the cheek except the periosteum. By this means the external surface of the superior maxilla is laid bare. Next, the periosteum along the inferior margin of the orbit is divided, and the orbital contents lifted upwards for a short distance, so as to define the position of the anterior portion of the spheno-maxillary fissure and the groove in the lachrymal bone. The cavity of the nose is also opened by detaching the

nasal cartilages from their lateral connection with the bone. As the operation proceeds, all blood vessels which are cut across are seized with pressure forceps and ligatured.

(*b*) *Division of bony connections, and removal of incisor tooth.*—With a Hey's saw or an appropriately shaped pair of strong cutting bone forceps the nasal process of the superior maxilla is divided by a cut which extends from the margin of the bony nasal aperture to the groove in the lachrymal bone. A second cut is made through the bridge of bone which separates the anterior extremity of the spheno-maxillary fissure from the external surface of the malar bone. Care should be taken in so doing that the malar prominence is left behind, in order to prevent too great a falling-in of the cheek afterwards. In dividing the nasal process of the superior maxilla, the attachments of the internal orbital ligament must be carefully preserved, otherwise

the suspensory ligament of the eyeball will be rendered more or less useless, and the eyeball will afterwards prolapse and come out upon the cheek.

With the dental forceps the central incisor tooth on the affected side is removed, and then with the scalpel the mucous membrane and periosteum along the floor of the nose on the affected side, and on the under surface of the hard palate, are divided, together with a small portion of the soft palate at its junction with the hard.

With a key-hole saw the alveolar and palatal processes of the superior maxillary and palate bones are divided, the saw being passed into the nose for this purpose. In performing this section of bone, care must be taken not to allow the saw to travel too far backwards, otherwise the base of the skull or the naso-pharynx may be injured.

(c) *Division of soft palate, and removal of jaw.*—With the scalpel the soft palate of the affected side is completely divided

FIG. 334.—Excision of upper jaw. Lion forceps.

in a transverse direction. Next, the lion forceps (Fig. 334) are taken, one blade placed in the orbit, the other in the mouth, and by a forcible wrenching and screwing movement the entire upper jaw is removed. This part of the operation (incision of the soft palate and removal of the upper jaw) should be effected as quickly as possible, on account of the severe hæmorrhage which may occur.

The jaw having been removed, the place it occupied is at once packed with sponges, so as to temporarily arrest bleeding. All blood is sponged out of the mouth and pharynx, and any bleeding vessels ligatured. In some cases it may be necessary to make use of a Paquelin's cautery, to arrest hæmorrhage from vessels in the bone. When all hæmorrhage has been arrested, the wound is packed with tampons of antiseptic gauze, and the skin incision closed by the insertion of a series of interrupted sutures of horse-hair or fine salmon-gut. The first of these sutures to be inserted should be the one at the internal canthus, the second the one at the margin of the lip, the third that

by the septum of the nose. All the sutures having been tied and cut short, the line of incision is covered with a collodion dressing.

After-treatment.—At the end of twenty-four hours the tampons of gauze are removed, the wound syringed out through the mouth, and packed as before. This process of dressing is repeated daily. The sutures are taken out at the end of five days or a week.

If the prominence of the malar bone has been removed, it will usually be found necessary to fit up the patient with an obturator or artificial upper jaw, so as to obliterate the flattening and consequent deformity of the cheek. If, however, the prominence of the malar bone is left, no artificial aid of this kind will usually be required.

2. *Partial excision of the upper jaw.*—Some surgeons have advocated leaving the orbital portion of the superior maxilla in cases of excision of the upper jaw. When, however, excision is undertaken for malignant growths of this bone, whether sarcomata or carcinomata, it is not advisable to leave this part of the bone behind, owing to the great liability to recurrence of the disease in the part left.

Partial excision of the upper jaw may, however, be practised with advantage, under the following circumstances:—

- (a) In removal of dentigerous cysts.
- (b) In removal of fibrous epulis.
- (c) For drainage of the antrum of the superior maxilla.
- (d) For removal of Meckel's ganglion.

The precautions to be observed in removal of portions of the upper jaw are described in the different chapters which deal with the individual operations.

In removing a part of the jaw on account of a growth, the teeth in the immediate neighbourhood should first be extracted, and then the entire portion of the bone involved in the growth, together with its periosteum, should be completely removed.

3. *Temporary excision of the upper jaw.*—Temporary or osteoplastic excision of the upper jaw has been practised in a few cases for removal of naso-pharyngeal tumours.

The details of the operation have been described in connection with the removal of naso-pharyngeal polypi (p. 347).

Excision of the lower jaw.—*Indications.*—Sarcoma of the inferior maxilla, carcinoma of the floor of the mouth extending into the inferior maxilla, and cystic epithelioma of the inferior maxilla.

Special instruments.—As for removal of the upper jaw.

Position.—The patient is placed in the dorsal position, with the head slightly raised by a sandbag. The operator stands on the affected side of the patient and the assistant on the opposite side.

Operation.—An incision is made through the lower lip, commencing at the junction of the red portion with the skin, and extending downwards to the symphysis menti, then along the horizontal ramus to the angle, and finally upwards as far as the level of the lobule of the ear. This incision extends down to the bone, except in the neighbourhood of the facial artery at the anterior border of the masseter muscle. The facial artery is isolated, tied in two places, and cut between. Then all the soft tissues of cheek, except the periosteum, are dissected up from the bone. The lower jaw is now sawn through half an inch external to the symphysis menti, an incisor tooth being first extracted, if requisite. The mucous membrane of the floor of the mouth, and the various muscles which are attached to the internal aspect of the lower jaw, are separated as far back as the angle. The horizontal ramus of the jaw is then grasped by the left hand of the operator, and the bone depressed so as to bring forwards and render evident the coronoid process and temporal muscle. The internal pterygoid is completely detached from the angle and ascending ramus, and the internal lateral ligament cut through where it is fixed to the internal margin of the inferior dental foramen. The inferior dental artery is picked up with pressure forceps just before it enters the foramen, and cut across, together with the corresponding nerve. The insertion of the temporal muscle into the coronoid process is now detached, and the pterygo-maxillary ligament divided. The ramus of the jaw is then further depressed so as to render prominent the condyle. The capsular ligament of the temporo-maxillary articulation is opened, and then divided all the way round, together with the external pterygoid muscle, which is inserted into the neck of the condyle at its interior and internal aspect. When this has been done, the jaw can be completely removed. Care

FIG. 335.—Excision of lower jaw.
a. Position of skin incision.

must be taken throughout the operation not to twist the lower jaw upon its axis, otherwise the internal maxillary artery, which lies in close relation with the neck of the bone, will run great risk of being injured. All through the operation the cutting edge of the knife should be kept close to the bone.

After the removal of the bone all bleeding vessels are tied, and the external wound is closed by the insertion of a number of sutures, and packed from the interior of the mouth with tampons of antiseptic gauze. It is in most cases advisable to place a drainage tube in the lower and posterior angle of the wound.

Partial excision of the lower jaw.—*Indications.*—(a) Epulis.

(b) Dentigerous cyst.

(c) Cases of inveterate ankylosis of the temporo-maxillary articulation, in which it is wished to make a false joint.

(d) Necrosis.

(e) Myeloid sarcoma.

(f) As a part of the operation in removal of the tongue for carcinoma, when the disease has extended to the bone.

In the majority of cases of removal of a portion of the lower jaw, especially when it is done for epulis or dentigerous cyst, the operation can be carried out through the mouth. In those cases, however, in which a considerable portion of the bone requires removal, or in which there is any difficulty in performing the operation through the mouth, an incision through the cheek, along the affected portion of the bone, should be made.

Position.—As for the preceding operation.

Operation.—The affected portion of the bone, together with the adjacent part of the floor of the mouth and internal surface of the cheek, are thoroughly exposed, either by opening the mouth with the gag and pulling aside the soft parts with retractors, or by making an incision through the tissues of the cheek overlying the portion of bone involved. Any teeth which may be present in the affected part of the jaw are removed. The mucous membrane and the periosteum are divided with a scalpel a short distance from the margin of the growth, and then with a chisel and mallet the affected portion of the bone is removed. If possible, a bridge of bone should be left along the inferior margin of the jaw, but this must not be done at the risk of leaving any diseased tissue behind.

After the arrest of hæmorrhage, the wound is packed with tampons of antiseptic gauze.

Removal of a wedge-shaped portion from the horizontal

ramus of the lower jaw.—This operation has been carried out in cases of closure of the lower jaw, dependent upon extensive contraction following burns or cancerum oris.

The wedge-shaped portion of bone is removed from the horizontal ramus immediately in front of the attachment of the masseter muscle, the apex of the wedge being at the alveolar margin and the base at the lower border. Fig. 336 shows the portion of bone which is removed in this operation.

Operation.—An incision 2 in. in length is made parallel with the horizontal portion of the lower jaw, commencing at the anterior border of the masseter and extending forwards towards the symphysis. The soft parts are divided, the facial artery being pulled downwards, and the external surface of the jaw exposed. The periosteum is now cut through, and the wedge-shaped piece of bone separated with a narrow-bladed saw. When the bone has been sawn through, the attachments of the mylo-hyoid muscle to its deep surface are cut through, together with the mucous membrane in the floor of the mouth. The separated piece of bone can then be completely removed.

FIG. 336.—Removal of a wedge-shaped piece from lower jaw.

a. Part to be removed.
b. Lines of saw cuts.

All bleeding is arrested, the interior of the wound packed with tampons of anti-septic gauze, and the skin incision closed by the insertion of a series of interrupted sutures.

Good results are said to have followed this operation. Mastication can only be performed on one side.

Excision of the clavicle.—*Indications.*—(*a*) Sarcoma of the clavicle; (*b*) acute necrosis; (*c*) some cases of backward dislocation of the sternal extremity of the clavicle may require excision of this portion of the bone.

Excision of the entire clavicle.—This is only necessary in cases of malignant growth.

Position.—The patient is placed in the dorsal position, with the shoulder on the affected side slightly raised by a pillow. The operator stands on the affected side and the assistant opposite to him.

Operation.—An incision is made over the entire length of the bone, commencing internally over the sterno-clavicular articulation and following the outline of the clavicle to the acromion. This incision divides everything down to the bone except the periosteum, namely, skin, fasciæ, platysma, and supra-clavicular nerves. The soft tissues are dissected upwards and downwards, the periosteum being left behind. When the bone has been sufficiently bared, the shaft is sawn through in a convenient situation, usually near the middle, with a Hey's saw, care being taken not to injure the important blood vessels and nerves which lie directly behind it. The sternal extremity is lifted up, the muscles and ligaments attached to its posterior surface

FIG. 337.—Excision of clavicle.
a. Position of external incision.

divided, and the capsular ligament of the sterno-clavicular joint cut through, after which it can be removed. The outer half of the clavicle is treated in a similar manner. The conoid and trapezoid ligaments are divided close to the coracoid process, the acromio-clavicular joint is opened and its ligaments cut through, and the bone removed.

Any bleeding vessels are ligatured, and the external wound closed by a series of interrupted sutures.

Removal of the diaphysis of the clavicle in cases of acute necrosis.—An incision is made over the middle of the bone parallel with its long axis, and all the soft tissues, including the periosteum, are incised down to the bone. By this means the necrosed portion is laid bare. With a pair of bone forceps the

diaphysis is divided transversely, and extracted in two halves with the aid of sequestrum forceps.

The space left by the removal of the diaphysis is thoroughly irrigated, then packed with strips of gauze, the extremities of which project from the external wound.

Excision of the sternal extremity of the clavicle.—An incision, usually about 2 in. in length, is made, commencing over the manubrium sterni and extending outwards over the sternal extremity of the clavicle. The soft tissues are divided until the anterior surface of the bone is exposed. The pectoralis major and the clavicular head of the sterno-mastoid are detached, and with a Hey's saw the shaft of the bone is divided at the outer extremity of the incision. The inner portion of the bone is seized with lion forceps and pulled forwards, and the muscles and ligaments attached to its posterior and inferior aspects cut through. These include the rhomboid ligament, the costo-coracoid membrane, and portions of the subclavius and sterno-hyoid muscles. Finally, the capsular ligament of the sterno-clavicular articulation is cut through with the scalpel, and the separated portion of the bone removed. All bleeding is arrested, and the external wound closed.

Excision of the scapula.—*Indication.*—Primary sarcoma of the scapula.

Position.—The patient is placed lying upon the sound side, turned a little more towards the ventral than the dorsal position, so as to fully expose the affected shoulder. The surgeon stands directly behind the patient and the assistant on the opposite side.

Operation.—An incision is made, commencing over the acromion process of the scapula and extending along the spine of the bone as far as the vertebral border. This incision divides all the soft tissues down to the bone.

A second incision is then made along the vertebral border of the scapula, commencing at the superior angle and extending downwards to the inferior angle.

Two flaps are then dissected up; they should, if practicable, include all the soft tissues except the periosteum, but care must be taken to avoid leaving any diseased tissue behind. These flaps are dissected outwards until the superior and external margins of the bone are laid bare. Next, the muscles along the superior and vertebral borders are detached; that is to say, the rhomboids, levator anguli scapulæ, and posterior belly of the omo-hyoid. This having been done, the vertebral border is lifted upwards and outwards, and the serratus magnus and

subscapularis muscles separated from the ventral aspect. The acromion process is sawn through at its junction with the spine, and drawn forwards. By this means the superior aspect of the shoulder-joint is exposed. The capsule of this joint is now divided, together with any of the adjacent muscles or tendons which still remain. The scapula is next pulled downwards and outwards, and the muscles attached to the axillary border and inferior angle cut through (teres major and minor, and long head of triceps). The scapula is now free and can be removed.

It is advisable, if possible, to leave behind the acromion process, together with the attachments of the deltoid and trapezius; but if the disease extends into this part of the bone, these muscles must be cut through and the bone removed at the acromio-clavicular joint.

All bleeding is arrested and the external wound closed in the usual manner.

Partial excision of the scapula.—This procedure may be requisite in cases of necrosis of a part of the bone or for exostoses growing from its surface.

No special directions can be given for this operation, since each case differs according to the position of the exostoses or the sequestrum.

Excision of the radius or of the ulna.—Removal of portions of these bones may be requisite in cases of malignant growth or of localised necrosis.

The operation is usually carried out by making an incision over the most exposed portion of the affected part of the bone, turning the soft tissues aside, and removing as much of the bone as is thought necessary.

The ulna is somewhat more accessible than the radius, on account of its nearness to the surface of the forearm.

Excision of a metacarpal bone.—A metacarpal bone is usually removed through an incision extending the entire length of its dorsal surface. The soft tissues are divided down to the bone, and separated and retracted on each side. The base is first disarticulated, the bone is lifted upwards and forwards, the muscular and ligamentous attachments on the palmar aspects separated, the head of the bone disarticulated, and the entire bone removed. In making the dorsal incision, care must be taken to avoid injury to any of the digital nerves.

Excision of a phalanx.—In the excision of a phalanx, an incision is made over the lateral aspect of the bone, somewhat nearer the dorsal than the palmar surface. The soft tissues are separated as in the removal of a metacarpal bone, and dis-

articulation is carried out, the proximal end of the bone being separated first.

Partial excision of a metacarpal bone, or of a phalanx.—In the removal of a portion of a metacarpal bone, or of a phalanx, the external incision is made in the same line as for the removal of the entire bone. The shaft is exposed, sawn through, and the diseased portion removed.

Excision of a rib.—*Indications.*—1. Empyema: (*a*) simple, following pleural effusion; (*b*) tuberculous; (*c*) due to actinomycosis of the base of the lung; (*d*) pyæmic. 2. Caries of a rib. 3. Primary new growth (sarcoma) of a rib. 4. Injury of the chest wall, with perforation of one of the intercostal arteries.

Special instruments.—Small saw, periosteal elevator, bone forceps, probe-pointed director, Volkmann's spoon.

Position.—The position of the patient depends upon which rib or ribs have to be excised: usually the patient is turned somewhat on the sound side, so as to expose the lateral aspect of the affected side of the chest. The surgeon stands on the affected side, and the assistant directly opposite to him, or the affected side may be allowed to project slightly beyond the edge of the table; the surgeon then sits down to operate.

FIG. 338.—Excision of rib.

a. Rib to be excised, showing its relation to skin incision.

Operation.—The portion of a rib which requires removal is first determined. The position and extent of the cavity which requires drainage is made out, and a portion of rib 3 in. in length is demarcated, which overlies the posterior and lower part of the cavity. This having been done, an incision is made over it and parallel with it. This incision should divide skin, fasciæ, muscles, and periosteum. The margins of the incision are retracted, and the periosteum separated from the internal and external aspects of the rib with a periosteal elevator. The rib itself is divided at each extremity of the incision, either with a pair of bone forceps or with a small saw; usually it is better

to employ the saw, for this is less likely to cause splintering. When the portion of rib has been removed, and it is desired to open the pleural cavity, as for the treatment of purulent collections within the chest, a probe-pointed director is pushed inwards through the floor of the space which the rib occupied, and made to pierce the periosteum, the thoracic fascia, and the parietal layer of the pleura. The blades of the dressing forceps are passed along the director, separated, and the opening enlarged. The interior of the chest can now be examined with the finger through this aperture, and any further measures which may be requisite carried out.

FIG. 339.—Excision of a rib. Relative position of structures in an intercostal space.

- a. Intercostal artery.
- b. Venae comites.
- c. Branch of intercostal artery.
- d. Nerve.
- e. Internal intercostal muscle.
- f. External intercostal muscle.

If the removal of a portion of one rib does not give sufficient access to the interior of the thorax, the margins of the parietal incision are well retracted, so as to expose the adjacent rib, either the one above or the one below. This is denuded of its periosteum, and a portion removed, as in the previous case. Under these circumstances it will be necessary to ligature the intercostal vessels. This is best effected by means of a curved aneurysm needle, which carries the ligature behind the vessels. Two ligatures should be applied—one at each extremity of the wound. When this has been done, the incision may be enlarged by cutting transversely across between the ligatures. Care must be taken not to injure the intercostal vessels in the process of detaching the periosteum from the bone. They lie in the grooves on the upper and lower aspects of the rib. The relative position of these structures is shown in Fig. 339. If the end of the periosteal elevator is kept

within the periosteal sheath, the vessels run no risk of injury.

When partial excision of one or more ribs is required in the treatment of an empyema, it is not necessary in most instances to remove more than about 2 in. of each. In caries of a rib, the diseased portion must be entirely removed. In cases of new growth it is generally necessary to take away much more extensive pieces of bone. The incisions, both through the soft tissues and through the bone, must in such cases be carried well wide of the growth.

When it is wished to drain the pleural cavity after the excision of one or more ribs, the fluid collection is first allowed to escape, and then a guarded indiarubber drainage tube of suitable size is pushed through the opening into the pleura and fixed in position, and abundant antiseptic absorbent dressings applied.

Excision of the patella.—*Indications.*—This operation may be requisite under the following circumstances:—

- (a) Primary new growths in the bone (sarcomata).
- (b) Tuberculous affections commencing in and limited to this bone.
- (c) As part of the operation of excision of the knee-joint.
- (d) Necrosis of the patella.

Special instrument.—Periosteal elevator.

Position.—The patient is placed in the dorsal position, with the affected limb fully extended. The operator stands on the outer side of the knee and the assistant opposite to him.

Operation.—A vertical incision 3 in. in length is made over the patella, commencing in the middle line about an inch above the upper border of the patella, and extending downwards almost to the tubercle of the tibia. This incision is deepened until the superficial surface of the bone is reached, the supra-patellar bursa being cut through and turned aside. The soft tissues are then dissected from the anterior aspect of the bone, and held aside with retractors. If the periosteum is not diseased, and the operation is not being performed for a malignant growth, it should be turned aside with the other soft tissues; but when it is the seat of tuberculous processes, or in cases of sarcoma, it should be removed along with the bone. The margins of the bone are defined, and then the fasciæ, muscular aponeuroses, and ligamentum patellæ are cut through. By these means the patella is separated from its connections with the soft parts, and can be removed. All hæmorrhage is arrested, the part of the knee-joint exposed in the wound sponged clean and dry, and the margins of the incision united by the insertion of a series of sutures. Usually, it will be advisable to dissect out the supra-patellar bursa in the early stages of the

FIG. 340. — Excision of patella. Position of external incision.

operation, since if it is left it is liable to impede the healing of the wound.

Aseptic dressings are applied, and the limb firmly fixed in splints.

Partial excision of the tibia.—Removal of a portion of the diaphysis of the tibia is occasionally required in cases of acute necrosis of the bone occurring in connection with acute infective osteomyelitis.

The operation is essentially of the nature of a sequestrotomy, and is usually performed after the expiration of some considerable time from the onset of the disease, when the periosteum has formed a sheath of new bone which encloses the dead portion.

Special instruments.—Chisel and mallet, in addition to the ordinary instruments for excision of a bone.

Position.—The patient is placed in the dorsal position, with the affected limb fully extended and lying somewhat upon its outer side. The operator stands on the outer side of the affected limb, and his assistant opposite to him.

Operation.—An incision, usually about 3 in. in length, is made over the middle of the affected portion of the bone. This is generally done by enlarging one of the sinuses which are already present. The soft tissues are divided down to the bone, and then the "involucrum" of new bone which surrounds the dead portion of the diaphysis is cut through, with chisel and bone forceps, in a vertical direction for the entire length of the incision. The margins of the wound are held apart with retractors, and the enclosed portion of bone extracted with sequestrum forceps. In order to facilitate the removal of the sequestrum, it will usually be found convenient to divide it transversely at the bottom of the incision with a pair of bone forceps, and to remove it in two halves.

The interior of the cavity in the bone from which the sequestrum has been extracted is thoroughly irrigated with an antiseptic solution, and then packed with tampons of antiseptic gauze.

In cases where the periosteum does not give rise to the formation of new bone after the sequestrum has been removed, it will be necessary to fill up the cavity either with a portion of bone from a limb amputated from another individual, or with decalcified bone, or with strips of twisted pewter wire. These substances appear to cause increased activity of the periosteum, and to promote the filling up of the cavity with new bone. In those cases where wire is used, it will be necessary to give the

patient an anæsthetic in order to extract it after it has become embedded in the newly-formed tissue.

Excision of the fibula.—*Indications.*—This may be necessary in cases of primary sarcoma of the bone, or more rarely in cases of acute osteomyelitis which has given rise to necrosis of a portion of the bone.

Operation.—A vertical incision is made over the postero-external border of the bone. The muscles are dissected away from their osseous attachments, and the affected part of the fibula exposed and removed.

The entire fibula may be removed without causing serious interference with the use of the limb.

Excision of the os calcis.—*Indications.*—(a) Tuberculous disease of the os calcis which is limited to that bone.

(b) Tuberculous disease of the astragalo-calcaneal articulation involving chiefly the os calcis.

(c) Acute necrosis of the os calcis, the result of acute osteomyelitis.

(d) Sarcoma primary in the os calcis.

Position.—The patient is placed in the dorsal position, with the affected foot supported on a sandbag with its outer surface upwards. The surgeon stands on the outer side of the affected foot and his assistant opposite to him.

Operation.—An incision is made, commencing at the inner border of the tendo Achillis immediately above its attachment to the os calcis, and extending across the heel and along the outer side of the foot to a point half an inch posterior to the prominence of the fifth metatarsal bone, the tendo Achillis being detached from its point of insertion. This incision divides all the soft tissues down to the os calcis. With a strong scalpel the soft tissues at the posterior and outer margin of the foot and the sole are dissected away from their attachment to the os calcis in the form of a single flap. The posterior portion of the os calcis is now grasped with lion forceps, and the entire bone forcibly pulled downwards, so as to render tense the ligaments of the astragalo-calcaneal joint. This is done by the assistant. The soft tissues at the upper part of the incision are dissected upwards, care being taken not to divide the peronei muscles, which should be held out of the way with retractors. The middle fasciculus of the external lateral ligament of the ankle-joint is cut through, and then the articulation between the inferior aspect of the astragalus and the upper surface of the os calcis is opened from the outer side. The very strong interosseous astragalo-calcaneal ligament is divided, and then the os calcis is

pulled further downwards and outwards, and cleared on its inner side. Next, the articulation between the anterior part of the os calcis and the cuboid is opened, by cutting through the ligaments from above. Finally, the calcaneo-scapoid ligament is divided, and the os calcis removed.

If more room is required in order to expose the inner aspect of the bone, the incision may be prolonged upwards along the inner margin of the tendo Achillis.

If the synovial membrane which lies between the astragalus and the calcaneum is diseased, it is dissected away.

Hæmorrhage having been arrested, the space previously occupied by the os calcis is packed with antiseptic gauze, and the external incision partially closed by the insertion of interrupted sutures.

FIG. 341.—Excision of astragalus. Skin incision.

Excision of the astragalus.—*Indications.*—(a) Some forms of inveterate talipes.

(b) Caries of the astragalus which is either limited to this bone or does not extensively affect the surrounding tissues.

(c) Some forms of disease of the astragalo-calcaneal joint, in which it is thought from the position of the sinuses that the affection chiefly involves the astragalus and not the os calcis.

(d) Cases of complete dislocation of the astragalus in which the bone cannot be replaced.

(e) Compound dislocation of the astragalus complicated with fracture, in which the bone cannot be satisfactorily replaced, and the severity of the injury is not sufficient to justify amputation.

(f) Sarcoma primary in the astragalus.

Operation.—An incision from 2 to 3 in. in length is made on the external aspect of the ankle (Fig. 341). It commences above immediately internal to the anterior border of the external malleolus and half an inch above the level of the ankle-joint, and extends in a downward and forward direction to a point on the dorsal and external surface of the foot over the cuboid bone, about an inch internal to the prominence at the base of the fifth

metatarsal bone. This incision is parallel with and posterior to the tendon of the peroneus tertius, and in front of the peroneus brevis. The skin and fasciæ, together with the anterior annular ligament, are divided until the bones are reached. The margins of the incision are dissected up and pulled well aside with retractors. This will expose the outer portion of the astragalus. The anterior fasciculus of the external lateral ligament of the ankle-joint and the anterior ligament of the same joint are divided. The foot is well extended and inverted, and the ligaments which fix the astragalus to the scaphoid on the dorsal aspect of the foot cut through. The astragalus is now seized with lion forceps, pulled strongly outwards, and its ligamentous connections on the inner side of the foot exposed and divided. When this has been done the bone can be pulled further outwards, and its posterior ligamentous attachments and the strong interosseous astragalo-calcaneal ligament cut through. The bone is now free, and can be removed. It should be remembered that no muscles are attached to the astragalus.

The astragalus can usually be removed in this manner in cases of talipes or of dislocation of the bone as a result of injury.

In removal of the bone for disease, however, the above incision does not give a sufficiently free exposure. In such cases a second incision is made on the inner side of the foot, immediately behind the tendon of the tibialis posticus.

When the bone has been removed, a gauze drain is placed in the interior of the wound, and the incision is closed by the insertion of interrupted sutures.

Excision of a wedge-shaped piece from the tarsus (cuneiform tarsectomy).—*Indications.*—An operation of this nature, involving the excision of a wedge-shaped piece from the tarsus, is necessary in certain forms of talipes equino-varus, talipes equinus, and talipes valgus, in which the bones themselves are considerably malformed, and in which other methods of treatment are not productive of a satisfactory result.

In cases of talipes equino-varus the base of the wedge is situated on the external and superior aspect of the foot, and comprises for the most part the cuboid bone. The apex is situated at the scaphoid on the inner side.

In talipes equinus the base of the wedge is towards the dorsum of the foot and the apex towards the sole.

In talipes valgus the base of the wedge is towards the inner margin of the foot.

The amount of bone which it is necessary to remove in these cases varies according to the amount of malformation present.

Often, however, it is requisite to take away portions of the cuboid, astragalus, and scaphoid, and occasionally of the other tarsal bones.

Special instruments.—Periosteal elevator, chisel and mallet.

Operation.—In the majority of instances, removal of a wedge-shaped portion of bone is effected through an incision situated upon the outer side and dorsal aspect of the foot over the most prominent part of the deformity.

An incision is made which commences over the dorsal and external aspect of the astragalo-scaploid joint, and extends downwards, outwards, and backwards towards the sole and the prominence of the heel (Fig. 342). This incision divides the skin and superficial fasciæ; the cutaneous portion of the musculo-

FIG. 342.—Cuneiform tarsectomy. Position and direction of external incision.

cutaneous nerve is sought for and defined at the inner angle of the wound, and the external saphenous nerve at the outer angle. When these nerves have been defined, they are retracted to the inner and outer sides respectively. The deep fascia is then cut through, and the muscles exposed.

In the inner angle of the wound the peroneus tertius will be seen; in the outer angle, the peroneus brevis and the upper border of the extensor brevis digitorum. These muscles are retracted to the inner and outer sides respectively, and the dorsal aspect of the tarsal bones exposed. The ligaments which fix these bones together are separated with the periosteal elevator, and the base of the wedge-shaped portion of bone which it is wished to remove exposed. This will usually consist of the greater part of the cuboid, the external and anterior portion of the os calcis, and the head of the astragalus, with possibly a small piece of the scaphoid. When the bones have been sufficiently cleared and freed from their ligamentous connections, the chisel and mallet are taken, and the portions of bone comprising the wedge removed.

Any adventitious bursa which has developed, should, if thick-

walled and conveniently reached, be dissected out and removed.

All bleeding having been arrested, the cut surfaces of bone are brought into apposition and the external wound closed in the usual manner. The limb is fixed in the rectified position on a suitable splint. After a few days the dressings are removed, the stitches taken out, and the limb encased in plaster.

Excision of a metatarsal bone, or of a phalanx.—Excision of these bones differs in no essential respect from that of the corresponding bone of the upper extremity. In the case of a metatarsal bone the incision is generally on the dorsal aspect of the foot; in the case of a phalanx, at the side.

CHAPTER XXVI.

EXCISION OF ARTICULATIONS.

By the term "excision of an articulation or joint" is understood the removal from the body, by the performance of a surgical operation, of a part or the whole of the tissues which enter into the formation of the joint which is under consideration.

Thus it generally happens that part or the whole of the ligaments, synovial membranes, interarticular fibro-cartilages, and articular surfaces and extremities of the bones are removed.

When only a part of the anatomical elements which enter into the formation of the joint are taken away, the operation is called a "partial excision"; and when all these tissues are removed it is known as a "complete excision." The partial operations are more commonly performed than complete ones, except in the case of tuberculous disease, when it not uncommonly happens that the whole of the joint tissues are excised.

Several distinct methods of performing "excision of a joint" are practised by surgeons. These are generally known as—

- (a) The open method.
- (b) The subperiosteal subcapsular method.
- (c) The osteoplastic method.

These different methods will now be separately discussed, and afterwards the excisions of the various individual joints will be described.

(a) *The open method.*—In the open method of performing the excision of a joint, an incision is made through the soft tissues overlying the articulation, in order to expose the diseased tissues and enable the surgeon to readily remove them. When the external surface of the capsular ligament has been reached, the soft tissues are turned aside by dissection, and the ligaments together with the articular extremities of the bones laid bare. The periosteum is left attached to the bones. This having been done, the articulation is excised, the ligaments

and portions of bone with their periosteum being taken away. This is the method used in extensively diseased joints, in which the disease has extended to all the tissues entering into the formation of the articulation. If only a portion of the joint elements are taken away, the operation is a "partial excision" performed according to the *open* method.

(b) *The subperiosteal subcapsular method.*—In this method of operation the periosteum which covers the extremities of the bones entering into the formation of the joint, and the capsular ligament with its localised thickenings, are turned aside at the same time as the more superficial soft tissues; the diseased synovial membrane and articular surfaces of the bones are removed, and finally the periosteum and the capsular ligament are replaced in their former positions. In order to do this effectively, the first incision is prolonged through the capsular ligament and the periosteum with which it is continuous, and then, with a rugine or a periosteal elevator, these structures are stripped from their attachments to the bones and turned aside. When this has been done, the interior of the joint cavity is exposed, and all diseased synovial membrane and articular cartilage can be removed. An excision performed according to this method is in reality a partial excision.

This form of operation is applicable to those cases of joint disease in which the synovial membrane and the articular cartilages are alone involved, as in the early stages of "tuberculous disease of joints," in some forms of joint affection dependent upon traumatic causes, and in some forms of ankylosis. It is not available in cases of extensive disease due to tuberculosis, or in any case of malignant disease of the bone, since in every case of this nature the periosteum must be removed.

(c) *The osteoplastic method.*—In addition to turning aside the periosteum of the articular extremities of bones and the ligaments, an attempt is made in "osteoplastic excision" to temporarily detach the bony prominences (tubercles, tuberosities, condyles, or trochanters) with the muscles and ligaments still fixed to them. This is effected by exposing the articulation as in the previous method, and then with a chisel and mallet the portions of bone to which the muscles and the ligaments, especially the lateral ones, are attached are chiselled through and turned aside, together with their attached soft tissues. When the diseased tissues from the interior of the joint have been removed, the bony prominences are fixed in their original position by means of bone or ivory pegs, or by sutures of silver wire or strong catgut. This method of performing excision of a

joint is of very limited application, and can only be made use of in the earliest stages of tuberculous disease, in some forms of ankylosis, and in traumatic affections.

The term "arthrectomy" is sometimes employed in place of "excision of a joint," complete excisions being known as "complete arthrectomies," and partial operations as "partial arthrectomies."

Arthrotomy is applied to that operation which consists in the incision of a joint, as for the evacuation of a collection of fluid, or the removal of a loose body. Arthrotomy, moreover, is the first stage in all partial or complete excisions.

Indications for excision of joints.

—(a) Tuberculous disease of a joint, which is not improving under ordinary palliative measures.

(b) Ankylosis of a joint, which either renders it useless on account of its immobility, or fixes it in a useless position.

(c) Some forms of injury to a joint, when there has been much splintering of bone, or when the fracture into the joint is comminuted, and the fragments cannot be replaced in position.

(d) Ecchondroses or exostoses of the articular extremities of long bones which extend into the joint cavity, and so make the articulation practically useless.

(e) Some forms of displaced cartilage which cannot be dealt with satisfactorily except by excision.

Arthrotomy is necessary for the removal of loose bodies, foreign bodies, detached portions of articular cartilage, displaced or dislocated inter-articular

cartilages, and for the evacuation of fluid collections within the joint cavity which cannot be satisfactorily dealt with in any other manner.

FIG. 343.—Instruments for excision of joints.

A Resection knife.

B Periosteal elevator.

Special instruments.—The instruments which are necessary for the excision of a joint are similar in nearly all instances, the chief difference being the form of saw and the size of the knife.

The following are requisite:—Resection knife, lion forceps, chisel and mallet, periosteal elevators, saw, and Volkmann's spoon. Suitable splints are also necessary.

The individual operations for the excision of joints will now be considered seriatim.

Excision of shoulder-joint.—The shoulder-joint is the articulation between the glenoid cavity of the scapula and the head of the humerus. In performing an excision of this joint, it may be necessary to remove either a part or the whole of the structures which enter into its formation. Usually, however, the operation is of the nature of a "partial arthrectomy."

Position.—The patient is placed in the dorsal posture, with the affected shoulder somewhat raised and projecting slightly over the margin of the table, and the limb drawn slightly outwards. The surgeon stands on the outer side of the diseased shoulder, the first assistant grasps the limb at the elbow (so as to be able to rotate it as required), and the second assistant takes up a position on the left of the operator.

Operation.—An incision is made which commences at the lower margin of the clavicle opposite the outer border of the coracoid process, and extends downwards in a direction parallel to the long axis of the humerus for a distance of about $3\frac{1}{2}$ or 4 in. This incision lies over the internal fibres of the deltoid muscle (Fig. 344). The skin and fasciæ are divided, care being taken to avoid the cephalic vein, which lies in the groove between the deltoid and pectoralis major muscles. This interval is defined if possible, and the cephalic vein pulled over towards the inner side, or, if the deltoid cannot be easily retracted outwards, its inner fibres are cut through. The pectoralis major is retracted internally, and the deltoid externally, the latter muscle being divided transversely immediately below its origin from the clavicle, if it is found to be necessary, in order to obtain a clear and uninterrupted view of the shoulder-joint. A muscular

FIG. 344.—Excision of shoulder-joint. Anterior incision.

branch of the acromial portion of the thoracic axis may require ligature at this stage. When these muscles have been well drawn aside by retractors, the antero-internal aspect of the capsular ligament will be visible in the bottom of the wound. The humerus is now rotated inwards by the assistant, so as to bring the bicipital groove of the humerus and the long tendon of the biceps into view. The capsular ligament of the joint is divided along the inner margin of the biceps tendon, together with the transverse humeral ligament which bridges over the bicipital groove and helps to hold the tendon in position. By this procedure the biceps tendon is separated from its sheath. With a retractor or blunt hook this tendon is drawn outwards, and at the same time the humerus is externally rotated by the assistant. This brings forwards the internal or lesser tuberosity of the humerus, together with the insertion of the subscapularis into it. This is separated from the bone either with a scalpel or a periosteal elevator. If the scalpel is used, a series of cuts is made parallel with the bicipital groove. Next, the biceps tendon is drawn towards the inner side, and the humerus is internally rotated by the assistant, so as to fully expose the external or greater tuberosity with its attached muscles. These are the supraspinatus, the infraspinatus, and the teres minor, in this order from above downwards. They are separated from their osseous connections in the same way as the subscapularis, care being taken not to divide the capsular ligament of the articulation in a transverse direction. In those cases in which the disease is limited to the synovial membrane and the articular extremities of the bone, it may be possible to detach the tuberosities with a chisel, and to turn them aside with their muscles attached to them. When the removal of the affected tissues has been accomplished, the tuberosities can be fixed in their original positions by the insertion of a few sutures. When the head of the humerus, together with as much of the shaft as is requisite, has been exposed, the upper extremity of the bone is forced out of the external wound and sawn across below the diseased area. In some cases it is possible to saw through the anatomical neck, while in others the surgical neck must be cut. When the upper extremity of the bone has been removed, the margins of the cut surface are rounded off so as to make a kind of artificial head to the bone. Next, all traces of diseased synovial membrane are removed, and then the glenoid cavity of the scapula is examined. If this is affected, the diseased portion is removed by bone forceps or a sharp spoon.

The interior of the articulation is now irrigated with an

antiseptic solution, so as to remove all bone dust or other débris.

A drainage tube is passed into the bottom of the wound, and the external incision is closed.

After-treatment.—The limb is supported in a sling for ten days or a fortnight, and then passive movements are commenced. These must be continued daily until the functions of the joint have become more or less completely restored. It is advisable to commence passive movements of the distal parts of the affected limb a day or two after the operation has been performed.

Some surgeons have made use of a posterior longitudinal incision for excision of the shoulder-joint, and others a U-shaped flap, the deltoid muscle being turned upwards, whilst others again have made a curved posterior incision and sawn through the acromion. None of these methods seem to be so satisfactory as the one described above, and they cause much more impairment of the functions of the limb.

Excision of the elbow-joint.—Three bones enter into the formation of the elbow-joint,—the lower end of the humerus and the upper extremities of the radius and ulna. The superior radio-ulnar joint is usually affected in diseased conditions of the elbow-joint, and requires excision as well.

An excision of the elbow-joint is in most cases complete, but occasionally it may be advisable to perform a partial operation.

Position.—The patient is placed in the dorsal posture, with the affected arm semiflexed at the elbow and resting upon the trunk. The hand is in a position of partial pronation. The surgeon stands on the outer side of the affected elbow and his assistant on the opposite side of the patient.

Operation.—An incision from 3 to 4 in. in length is made along the posterior aspect of the limb, slightly nearer the ulnar than the radial margin (Fig. 345). This incision commences on the dorsal aspect of the forearm about 2 in. below the elbow-joint, and extends upwards to a similar distance above. The prominence of the olecranon is situated opposite the middle of the incision. The skin, fasciæ, and muscles are divided down to the posterior aspect of the bones. In the upper half of the incision the triceps is cut through, and in the lower half the fibres of the anconeus near the posterior border of the ulna are exposed. A flap, consisting of skin, fasciæ, and muscles, is now dissected from the bones towards the outer side. In making this flap, the edge of the excision knife, or the periosteal elevator, should be kept close to the bone, and all cuts made parallel with the external incision. This flap consists above of one-half of the

triceps, the upper part of the anconeus, and the origins of the extensor muscles which are attached to the external condyle of the humerus, and below of the rest of the anconeus and the continuation downwards of the extensor muscles. If the disease has not extended to the external condyle, this process of bone may be cut through with a chisel, and the attachments of the extensor muscles partially preserved.

Next, a similar flap is turned up from the inner side. In dissecting up this flap, great care must be taken not to injure the ulnar nerve. It lies in the groove between the inner margin of the olecranon process of the ulna and the internal condyle of the humerus. If the edge of the knife is kept close to the bone, and each cut is made in the direction of the course of the nerve, there is little risk of injuring it. The internal condyle

FIG. 345.—Position of patient, and line of external incision in resection of right elbow-joint.

is cleared in a manner similar to the external, or in suitable cases it may be cut through and turned aside with the muscles attached.

The joint is flexed by the assistant, and then the posterior part of the capsular ligament is cut through immediately above the olecranon, and the joint cavity opened. The lateral ligaments are usually turned aside along with the muscles. The extremities of the bones are now turned out, and fully exposed. A few slight cuts with the knife will sufficiently free them from the soft tissues, and then they are ready for the performance of "bone section."

The assistant who has charge of the arm thrusts upwards the forearm, so as to make the upper extremities of the radius and ulna project beyond the lower end of the humerus. The olecranon is then grasped by an assistant with a pair of lion

forceps, and steadied whilst the surgeon makes the section with a saw from behind forwards. The olecranon process of the ulna, together with the articular portion of the coronoid, are removed, and also the head of the radius, below the articular surface but above the attachment of the biceps tendon. The

- d.* Lower " " "

lower end of the humerus is now protruded, the trochlear portion grasped with lion forceps, and the section made with the saw along a plane which is above the articular surface. The epiphyseal line is below the level of the section in nearly all cases. When the bones are being divided with the saw, the

soft parts should be protected from injury by broad flat retractors held by an assistant.

When the articular ends of the bones have been removed, the space which is exposed is examined for portions of diseased tissue, and if any are found, they are removed by scraping with a sharp spoon.

All bleeding is arrested, and the external wound closed by the insertion of a series of interrupted sutures. If a large cavity has been made owing to removal of considerable quantities of tissue, or if there is much oozing of blood from the incised surfaces, a drainage tube is passed into the bottom of the wound, and the free extremity brought through an angle of the external incision left open for the purpose.

Antiseptic dressings are next applied, and the limb placed in a right-angled position and bandaged to a splint; or it may be fixed to a straight splint, and kept in the extended position for the first few days. In all probability the latter method is the better.

After-treatment.—The limb is maintained at rest for two days, and then passive movements of the finger and the wrist are commenced. At the expiration of about ten days or a fortnight, passive movements at the elbow are commenced, and continued daily until good movements have been restored. It is often necessary, especially in the case of children, to place the patient under an anæsthetic before commencing these movements at the elbow-joint.

There appears to be less risk of producing a “flail-like” joint when the limb is put up in the extended position, than when it is placed on a right-angled splint.

Excision of the elbow-joint through an external slightly-curved incision.—Köcher recommends that an incision 5 in. in length should be made on the outer side of the arm. It commences at a point opposite the upper part of the external supra-condylar ridge of the humerus, and 2 in. above the level of the articulation, and extends downwards along the outer aspect of the limb as far as the head of the radius; then it crosses the extensor aspect of the forearm in an oblique direction to a point on the posterior border of the ulna about 3 in. below the elbow-joint—this part of the incision corresponds to the inferior and external margin of the anconeus muscle; the incision terminates by curving inwards for a short distance (Fig. 348). The incision is extended to the bones and the external aspect of the elbow-joint. In its upper part it passes between the external head of the triceps posteriorly and the supinator longus and extensor group

of muscles anteriorly; and in its lower segment it is situated between the outer margin of the anconeus posteriorly and the extensor carpi ulnaris anteriorly. The external lateral ligament, the outer part of the orbicular ligament, and the adjacent portion of the capsule which is attached to the external condyle, are detached and retracted forwards. The forearm is next forced inwards, so as to dislocate the articular surfaces outwards. The internal lateral ligament is next separated, and then the excision of the joint can be readily performed.

The triceps and the anconeus are separated from the bone, the olecranon being cut through, if not too extensively diseased, and drawn towards the ulnar side, in the form of a flap. This gives a good exposure of the joint. The bones are then sawn as in the previous operation.

Kocher recommends that the olecranon should be sawn in a curved direction, so as to preserve a lever for the action of the triceps muscle, and help to prevent the partial dislocation of the forearm forwards.

Other incisions have been advocated for exposing the elbow-joint in excisions, but none of them are so satisfactory as the two above described, and in my opinion the operation first described is the one to be preferred in nearly all cases.

Excision of the radial portion of the superior radio-ulnar joint (excision of the head of the radius).—This operation is occasionally necessary in old-standing cases of dislocation of the head of the radius, in which the bone cannot be replaced and maintained in its normal position.

Operation.—The position of the head of the radius is first defined, and then a vertical incision 2 in. or more in length is made over the most projecting portion of the bone, and in a direction parallel with the long axis of the forearm. This incision is deepened until the bone is reached. The orbicular ligament which surrounds the head of the radius is divided, and the soft tissues held aside with retractors. The radius is next cut through at the level of its neck either with a fine saw or

FIG. 348.—Excision of elbow-joint through an external incision. *a*. Position of skin incision.—After KOCHER.

bone forceps. The section should be made above the bicipital tuberosity, and care should be taken to avoid injury to the radial and posterior interosseous nerves.

In the after-treatment, passive movements must be commenced immediately the external wound has healed, so as to avoid the formation of adhesions and the limitation of movement.

Excision of the wrist.—The wrist-joint, from a surgical point of view, may be considered to comprise the series of articulations which lie between the distal extremities of the radius and the ulna and the proximal ends of the metacarpal bones. There are in reality three transverse joints included

FIG. 349.—Synovial membranes of the carpus.

under this term,—the radio-carpal joint, the transverse carpal joint, and the carpo-metacarpal joint,—in addition to the small joints between the individual bones of each row of the carpus. There are six (sometimes only five) separate synovial membranes in connection with these joints, the extent of which is shown in Fig. 349. An excision may be either complete or partial, according to the number of bones removed.

The operation has been performed for tuberculous disease of the wrist, for injuries such as compound fractures and dislocations and gunshot wounds, and in some forms of rheumatic affections of the joint.

Position.—The patient lies on the operation table in the dorsal posture, with the affected limb at right angles to the trunk, and resting upon a second smaller table. The operator seats himself opposite the affected hand, his assistant being opposite him.

Many operations have been practised for excision of the wrist. The best appear to be those which are performed through dorsal incisions, and the most satisfactory of these is the one described by Ollier. The following operation is based upon Ollier's method :—

Operation.—Excision of the wrist may be divided into the following stages :—(a) Skin incisions, and exposure of the bones ; (b) removal of the bones ; (c) closure of the external wound.

(a) *Skin incisions.*—Two incisions are made, one on the radial and the other on the ulnar side of the dorsal aspect of the limb. The radial incision commences on the dorsal surface of the metacarpal bone of the index finger at a point opposite the middle of the shaft, and extends upwards along the radial margin of the outer tendon of the extensor communis digitorum to a point situated at the centre of a line joining the styloid processes of the radius and ulna. Beyond this level it is prolonged upwards in a vertical direction for about 1 in. or a little more (Fig. 350, a). This incision measures about 3 or 4 in. in length, one-third being situated above the line joining the two styloid processes, and two-thirds below it. The incision divides the skin and fasciæ with some of the fibres of the posterior annular ligament, and lays bare the radial tendon of the extensor communis digitorum. This muscle is retracted towards the ulnar side, and the incision deepened until the bones are reached, care being taken not to divide the tendon of the extensor carpi radialis brevis, which is inserted into the dorsal aspect and radial side of the base of the

FIG. 350.—Excision of wrist.

Skin incisions.

a. Radial incision.

b. Ulnar incision.

third metacarpal bone. In the upper part of the incision it is necessary to separate the radial margin of the extensor indicis from the ulnar border of the extensor secundi internodii pollicis, which can be recognised by its oblique direction. The extensor indicis and the extensor communis digitorum are drawn towards the ulnar side with retractors, and the extensor secundi internodii pollicis and the extensor carpi radialis brevis towards the radial side. With the periosteal elevator or ruge the dorsal aspect of the bones is laid bare by detaching the posterior ligaments and the periosteum.

Ulnar incision.—An incision is made along the radial margin of the tendon of the extensor carpi ulnaris tendon, commencing at a point opposite the middle of the shaft of the fifth metacarpal bone, and extending upwards to a point about 1 in. or a little more above the prominence of the styloid process of the ulna (Fig. 350, *b*). The skin and fasciæ are divided, care being taken to avoid the branch of the ulnar nerve to the dorsum of the little finger, and the interval between the extensor carpi ulnaris and the extensor minimi digiti exposed. These muscles are exposed and pulled aside, the former towards the ulnar margin of the limb, and the latter towards the radial. The dorsal aspect of the lower portion of the ulna, the cuneiform, the unciform, and the proximal part of the fifth metacarpal bone, will now be exposed. The ligaments and periosteum are divided with the scalpel, and then separated from their bony attachments with the ruge.

(*b*) *Removal of the bones.*—When the carpal bones have been separated from their periosteal and ligamentous connections, each one is seized separately with forceps and removed. It is most convenient to remove the bones from the radial side of the carpus first, and then to remove those on the ulnar side through the ulnar incision. On the radial side the trapezium should be left if it is not diseased. The articulation between this bone and the base of the first metacarpal has a separate synovial membrane, hence it often happens that it can be safely left. The pisiform bone may be disarticulated, and the unciform process of the unciform cut through, and both left if not diseased.

Removal of the extremities of the radius and ulna.—The shafts of these bones are now cleared of their periosteum for about half an inch, or a little more if requisite (according to the extent of the disease process), and then made to protrude through the radial incision. With a narrow saw the ends are removed beyond the limits of the articular surfaces. If they

are not extensively affected, it may be sufficient to scrape them with a sharp spoon.

Removal of the proximal extremities of the metacarpal bones.—These are protruded through one of the dorsal incisions, usually the ulnar, and the articular ends removed with a fine saw. The section of these bones is generally made just beyond the articular surfaces. The connection of the first metacarpal with the distal surface of the trapezium is not interfered with if possible.

(c) *Closure of the external wound.*—The cavity from which the bones have been removed is sponged dry, freed from all bone débris, and the margins of the skin incisions united by the insertion of a number of interrupted sutures. Part of the ulnar incision is left open, and through this a short drainage tube is passed inwards. Antiseptic dressings are then applied.

The limb is fixed in a position of slight dorsiflexion, with the fingers gently flexed, by the application of a splint of suitable shape. Fig. 351 is a form of splint which will be found to answer the purpose.

FIG. 351.—Excision of wrist. Splint for use after operation.

The fingers should be passively moved during the time that a splint is worn. In most cases it is necessary for the patient to wear the splint from three to six months.

When the splint has been discarded the patient should wear a leather wristlet.

The results of excision of the wrist-joint have not been good. A certain number of cures have been effected, but often, especially when the operation is performed for tuberculous disease of the carpus, the disease recurs, necessitating a second excision or an amputation.

Excision of a metacarpo-phalangeal joint.—This operation is occasionally performed, most commonly in connection with the metacarpo-phalangeal joint of the thumb or that of the little finger.

Operation.—An incision from $1\frac{1}{2}$ to 2 in. in length is made along the lateral aspect of the affected joint, the centre of the incision being opposite the joint. The incision should be situated a little nearer the dorsal than the palmar aspect of the digit. The soft tissues are divided down to the bone, the lateral ligament is divided, and the periosteum and the tendons turned

aside. The ends of the metacarpal bone and the phalanx are protruded through the incision and then removed with a fine saw.

In the case of the thumb the incision is placed on the radial side, in the little finger on the ulnar side, and in the case of the other metacarpal bones on either the radial or ulnar side, whichever is the more convenient.

The incision is closed with sutures, and the finger fixed to an anterior splint. As soon as the wound has healed, passive movements are commenced, usually at the end of a week or ten days.

Excision of an interphalangeal joint.—This operation is similar to the one described for a metacarpo-phalangeal joint. In some cases the operation will be facilitated by making an incision on each side of the joint. Usually, however, one lateral incision will be found sufficient.

Excision of the hip-joint.—The hip-joint is the articulation between the head of the femur and the acetabular cavity of the os innominatum. The capsular ligament of the joint is attached above to the rim of the acetabulum and the transverse ligament which bridges over the cotyloid notch, and below to the anterior inter-trochanteric line in front, and the neck of the femur half-way between the margin of the articular surface and the posterior inter-trochanteric line behind. From this it will be understood that the ligamentous attachments and the synovial membrane of the joint extend much farther down the femur anteriorly than posteriorly. The anterior portion of the capsule is much thickened by the ilio-femoral ligament or the Y-shaped ligament of Bigelow. In the interior of the joint there is a ligament fixing the head of the bone to the margins of the cotyloid notch. This is called the ligamentum teres. A large bursa, which is called the psoas bursa, is situated between the anterior aspect of the joint and the deep surface of the ilio-psoas muscle. This often communicates with the cavity of the hip-joint through an aperture in the anterior portion of the capsule.

An excision of the hip-joint is usually only partial, the femoral elements being the parts which are generally removed. The joint requires excision most commonly in tuberculous affections, and also more rarely for ankylosis in a faulty position, or for inflammatory affections, and in some cases of gunshot wounds. Ankylosis of this joint in a faulty position is usually treated by osteotomy of the femur, as described on p. 473.

Excision of the hip-joint may be carried out (*a*) through a postero-external incision, or (*b*) through an anterior incision. The former is more suitable for extensive operations, and the

latter for the less severe ones in which the disease is limited to the upper part of the femur.

Excision of the hip-joint through a postero-external incision.—*Position.*—The patient lies upon the sound side, with the diseased hip-joint flexed at half a right angle. The operator stands behind the patient, the chief assistant opposite to him, and a second assistant at the foot of the table holds the affected limb of the patient.

Operation.—The operation may be divided into the following stages:—

(a) *External incision and exposure of capsule.*—An incision about 4 in. in length is made, commencing at the lower border of the great trochanter of the femur, and extending upwards and backwards towards the posterior superior spine of the ilium (Fig. 352). The upper portion of this incision should be parallel with the direction of the fibres of the gluteus maximus muscle, and may be slightly curved if necessary. The incision divides the skin, fasciæ, and gluteal aponeurosis in the lower half, and the gluteus maximus in the upper. These structures, after being divided, are held aside with retractors, and the interval between the upper border of the pyriformis and the lower border of the gluteus medius muscle sought. When found, this is opened up and the capsule of the hip-joint laid bare. The assistant who has charge of the limb rotates it outwards, so as to bring the anterior part of the great trochanter into the wound. The surgeon then separates the attachments of the gluteus medius and minimus from the external and anterior aspects of the bone with a rugine. The limb is next rotated inwards, and the pyriformis, obturator internus and two gemelli, and the obturator externus, are separated in a similar manner. The obturator externus is inserted into the bottom of the digital fossa of the femur, and the other muscles to the top of the trochanter.

FIG. 352. — Excision of hip, through a postero-external incision.

a. Position of incision.

(b) *Division of capsule and exposure of the interior of the joint.*—The capsular ligament is incised in a direction parallel with the upper border of the pyriformis, and stripped backwards and forwards with the rugine or knife, if requisite. The soft

parts are well retracted by the assistant, so as to thoroughly expose the interior of the joint. The head of the femur is dislocated through the opening in the capsule, the ligamentum teres being cut through if necessary.

(c) *Removal of diseased parts.*—The neck of the femur is sawn through beyond the limits of the diseased tissue, any sequestrum which may be present removed, and then all thickened or pulpy synovial membrane taken away by dissection or scraping with a sharp spoon. The interior of the joint is flushed out with an antiseptic lotion, and an examination of the acetabulum made. If the disease has involved this part of the joint, all affected portions are scraped away.

FIG. 353.—Excision of hip-joint through an anterior incision.

a. Position of incision.

(d) *Closure of external wound.*—The interior of the joint is again washed out, a drainage tube is passed down into the bottom of the cavity, and the external incision closed by the insertion of sutures in the usual manner.

Dressings are applied, and the patient placed on a splint. In the case of a child a double Thomas's hip-splint is the best; for an adult a Hodgen's or a Bryant's.

After-treatment.—The patient must be kept at rest for five or six weeks, and then he can be allowed to get about, a single splint being substituted for the double one. It will be necessary, however, for the splint to be worn for nine or twelve months. If the splint is left off too early, the ligaments in the

region of the hip become elongated and the functions of the limb considerably impaired.

Excision of the hip-joint through an anterior incision.

Position.—The patient is placed in the dorsal position on the operation table, with the affected hip near the edge. The surgeon stands on the outside of the affected joint, and his assistant on the opposite side.

Operation.—An incision 3 in. in length is made on the antero-lateral aspect of the thigh, commencing above about half an inch below the anterior superior spine of the ilium, and extending downwards and slightly inwards (Fig. 353). This incision divides skin and fasciæ, and then by dissection the interval between the rectus femoris and sartorius on the inner side, and the

tensor fasciæ femoris and gluteus medius and minimus on the outer side, is opened up, and the surface of the capsule of the articulation exposed. The capsule is then incised, and the interior of the joint opened. Often, one or more abscess cavities are met with, in which case their interior is thoroughly irrigated before proceeding further. When the joint cavity has been opened it is irrigated, and the diseased portion of the femur removed by sawing through the bone *in situ* beyond the limits of the disease. Any other diseased parts of the joint are removed, as in the previous operation; and, after washing away all traces of blood, etc., by irrigation, a drainage tube is introduced and the external wound closed. In tuberculous cases it is advisable in many cases to fill the interior of the wound and remains of joint cavity with a sterilised emulsion of iodoform.

The further treatment of the case is similar to that after excision through a postero-external incision.

The disadvantages of this operation are the difficulty in obtaining satisfactory drainage, and the limited exposure of the joint during the performance of the operation.

Excision of knee-joint.—The articular surfaces of three bones enter into the formation of the knee-joint. These are the lower extremity of the femur, the posterior aspect of the patella, and the upper end of the tibia. In performing a complete excision all these surfaces are removed.

The object of the surgeon after excision of the knee-joint is to obtain complete ankylosis of the tibia and the femur. The operation is usually performed for tuberculous disease. Ankylosis of the joint in a faulty position, some forms of compound dislocation of the joint, and gunshot wounds, may also require this form of treatment.

Partial excision of the knee-joint, or so-called "arthrectomy," is sometimes performed, and in these cases the surgeon aims at producing a movable joint. The operation of complete excision will be described first, and the partial operation afterwards.

Excision of the knee-joint (complete).—*Position.*—The patient is placed in the dorsal posture on the operation table, the affected limb being close to the edge, and the distal half of the leg projecting beyond the end of the table. The surgeon stands on the outer side of the affected limb and the assistant opposite to him. A second assistant stands at the end of the table, and holds the limb in the position required.

Operation.—The operation of excision of the knee-joint may be divided into several stages, as follows:—

(a) *External incision.*—The limb being held slightly flexed at

the knee-joint by an assistant, the positions of the internal and external condyles of the femur are exactly defined. An incision is made, commencing in the case of the right leg immediately behind the adductor tubercle, then extending in a curved direction downwards to the upper border of the tubercle of the tibia, and thence upwards to a point immediately behind the prominence of the external condyle (Fig. 354). This incision divides the skin, superficial fascia, and deep fascia, which is here thickened on account of expansions of the vasti muscles having been inserted into it, and the flap of soft tissues thus marked

FIG. 354.—Excision of knee-joint. Position and direction of skin incision.

- a. Line of skin incision.
- b. Position of adductor tubercle.
- c. Prominence of external condyle.
- d. Tubercle of tibia.

out is dissected upwards until the superior margin of the patella is reached.

(b) *Opening of the knee-joint and free exposure of articular surfaces, and division of ligaments.*—The aponeurosis of the quadriceps extensor muscle is divided along the upper border of the patella until the external surface of the synovial membrane is visible. The synovial membrane, including the large pouch which passes upwards underneath the quadriceps, is dissected away from its connections with the deep aspect of the muscles, and then from the anterior and lateral aspects of the femur, until the margin of the articular cartilage is reached. The joint is now opened from above. The incision is extended laterally, and the capsule and the lateral ligaments are divided;

the patella is turned downwards, but should not be removed at this stage, as it affords a useful means of steadying the tibia when the bones are being sawn. The large bursa which lies between the ligamentum patellæ and the tibia is dissected away, and the head of the tibia cleared anteriorly as far as the margin of the articular surface. The assistant flexes the knee, so as to more fully expose the interior of the joint. The surgeon detaches the crucial ligaments from their attachments to the tibia and femur, and removes them together with the interarticular cartilages. The limb is still further flexed, and the posterior and lateral aspects of the femur and the tibia cleared for a short

distance by a series of small strokes with the knife. The bones are now ready for section.

(c) *Section of the bones.*—The knee-joint is bent at a right angle, the sole of the foot resting on the table; the posterior aspect of the condyles of the femur is supported on the upper end of the tibia, and the limb is held firmly in this position by an assistant. The soft parts are retracted, and the section of the femur is made in an antero-posterior direction. Care must be taken that the saw is held in such a position that the cut surface corresponds to the plane of the articular surface. An ordinary amputation saw with movable back is the most convenient to employ in most cases, but a Butcher's

FIG. 355.—Excision of knee-joint. Saw for section of bones.—BUTCHER.

saw (Fig. 355) is required when one of the bones is to be specially shaped to fit the other. Not more than 1 in. of the lower end of the femur should be removed, otherwise there is danger of injury to the epiphyseal cartilage, an accident which might be followed by considerable shortening of the limb, if the operation were being performed on a young individual (Fig. 322).

The upper end of the tibia is next made to project beyond the femur, the leg being held in a vertical position with the foot still resting on the table, and the saw-cut is made in a horizontal plane from behind forwards.

The two sawn surfaces of bone must be in a plane corresponding to that of the articular surfaces which are removed, otherwise when the bones are brought into apposition the limb will be found to be bent at an angle.

The patella with its attached ligamentum patellæ and portions of the capsule and synovial membrane are taken away, the ligamentum patellæ being cut through at its attachment to the tubercle of the tibia.

The posterior portion of the joint is now examined, and any remaining portions of synovial membrane

or thickened bursæ removed. The bursa underneath the tendon of the popliteus muscle should be examined, and in nearly all cases it will be advisable to dissect it out, since it invariably

communicates with the cavity of the knee-joint. Any other bursæ which are thickened or communicate with the cavity of the knee-joint should be treated in a similar manner.

(d) *Coaptation of the ends of the femur and tibia, and application of a suitable splint.*—The best splint for use after excision of the knee is the one represented in Fig. 357. This splint is applied, fixed in a position by careful bandaging, and the extremities of the bones brought into exact apposition.

Various methods of pegging or wiring the ends of the bones together have been employed, but they are rarely necessary.

It is advisable in most cases to fix the limb on the splint before closing the external wound with sutures.

(e) *Closure of external wound.*—The margins of the incision through the skin and fasciæ are brought into exact apposition, and fixed by the insertion of a number of interrupted sutures. The inner and outer angles of the wound should be left slightly open, so as to allow of the escape of any exudations which may take place.

Antiseptic dressings are then applied. It is not usually necessary to introduce a drainage tube if the angles of the wound are left open as above.

After-treatment.—The limb is kept at rest on the splint for about six weeks, until firm union has occurred.

At the end of about three months, in favourable cases, the patient may be allowed to use the limb in which the knee-joint has been excised.

Excision of the knee-joint (partial).—This operation has been called “arthrectomy,” or “*eration*” of the joint. The best term is, I think, *partial excision*; but if it be preferred, *eration* may be used.

Indications.—The operation is performed in early cases of tuberculous disease in which only a part of the anatomical elements of the joint are involved in the pathological process. It is recommended that it should be done when the synovial membrane alone is involved.

Operation.—A transversely curved incision is made across the front of the knee, as in excision. The ligamentum patellæ is cut through at the lower part of the incision, and the joint cavity opened from below. The ligamentum patellæ, the patella, and the capsule of the joint are lifted upwards, and the interior of the joint exposed. All thickened or pulpy synovial membrane is then dissected away, or removed by scraping with a Volkman's spoon, any infiltrated ligaments or interarticular cartilages are cut away, and if the articular ends of the bones are affected,

the involved areas are thoroughly scraped, so as to get away all diseased tissue.

When the joint has been freed from all traces of affected tissue, the interior is well irrigated with an antiseptic solution. The ligamentum patellæ and the margins of the incision in the capsule are united by the insertion of a series of silk sutures. Next, the external wound is closed in the usual manner, and the limb put up in a suitable splint.

When complete healing has taken place, passive movements are commenced, and an attempt made to get a movable joint.

Kocher recommends that the first incision should be similar to that recommended for "complete excision," and that, after the flap of skin and fasciæ has been dissected up, the knee-joint should be opened on each side of the patella, and all necessary manipulations carried out through these incisions. The advantage of this method is that the ligamentum patellæ is not interfered with, and when healing has taken place a much stronger articulation is left. He claims also that a better exposure of the interior of the joint is obtained by this method. Kocher's arguments appear to have considerable weight, and if a partial excision of the knee-joint is to be attempted, it is probable that his operation will lead to a satisfactory result in well-selected cases.

Excision of the ankle-joint.—The bones which enter into the formation of the ankle-joint are the inferior articular extremities of the tibia and fibula, and the superior and lateral articular surfaces of the astragalus. The ligaments which hold these articular surfaces together are anterior, posterior, external lateral (with three fasciculi), and internal lateral. There is a single synovial membrane.

Owing to the complicated nature of the joint, excision has not been followed by such good results as has been the case in other joints.

Indications.—The chief clinical conditions which may necessitate an excision of the ankle-joint are—(a) Tuberculous disease, either originating in the joint, or extending to it from one of the adjacent bones; (b) some cases of compound dislocation of the joint with fracture of one or more of the bones; (c) some forms of suppuration of the joint; (d) some cases of talipes.

Many varieties of operation have been carried out by different surgeons in excising the ankle-joint. The best operation appears to be that which has been recommended by Kocher and Reverdin. In this procedure the joint is excised through a

single incision situated on the anterior and external lateral aspects of the foot.

Position.—The patient is placed in the dorsal position on the operation table, with the affected foot lying on its inner side and supported by a sandbag covered with a sterilised towel. The foot should be near the extremity of the table. The operator stands on the outer side of the affected foot, the chief assistant stands opposite to him on the sound side, and a second assistant at the end of the table. The duty of the second assistant is to hold the foot and manipulate it as required by the surgeon.

Operation.—An incision is made across the dorsal and external lateral aspects of the foot (Fig. 358). It commences at a point half an inch below the centre of the ankle-joint, extends outwards and backwards to the lower margin of the external malleolus, and then upwards and somewhat inwards to the fibular margin of the tendo Achillis. The incision is usually from 3 to $3\frac{1}{2}$ in. in length, and is curved in outline, the concavity looking upwards and towards the tibial margin of the limb.

FIG. 358.—Excision of ankle-joint. Position of skin incision.

The skin and fasciæ are divided, the external portion of the musculo-cutaneous nerve sought for in the inner part of the wound, and when found retracted to the tibial side, and the short saphenous nerve and vein in the outer part behind the external malleolus. When the deep fasciæ and the fibres of the anterior and external annular ligaments have been cut through, the tendons of the extensor muscles will be exposed in the anterior part of the wound, and those of the peronei in the posterior part.

With a rugine or periosteal elevator the deep processes of the external annular ligament, and the peronei tendons with their sheaths, are separated from the external aspect of the os calcis and peeled backwards. In very inveterate cases of club-foot, it

may be necessary to cut through these tendons, which section must be repaired by suture at the end of the operation. Next, the extensor tendons at the anterior angle of the incision, the processes of the anterior annular ligament, and the anterior ligament of the ankle-joint, are separated with the rugine, and retracted towards the tibial side. The external lateral and the posterior ligaments are then treated in a similar manner, by detaching them from their bony attachments. When these structures have been detached, the joint will be opened on its posterior, internal, and anterior aspects. The internal lateral ligament is left undisturbed.

The foot is now forcibly adducted towards the tibial side, and completely dislocated inwards until the plantar surface lies in contact with the skin on the inner side of the leg. The head

FIG. 359.—Synovial membranes of tarsus and metatarsus.

of the astragalus and the lower extremities of the tibia and fibula appear in the wound.

A saw of suitable shape is taken, and the diseased portions of the exposed bones removed. All thickened or pulpy synovial membrane and thickened tendon sheaths are removed by dissection. If the astragalus is extensively involved in the disease, or if the synovial membrane of the astragalo-scaphoid joint is affected, it will be necessary to remove the entire astragalus along with all other infiltrated and diseased tissues.

All bleeding is now arrested, and the foot brought into its original position. If the peroneal tendons have been divided, the cut ends are sutured together. The ligaments on the external aspect of the joint are united with sutures, if possible, and the external wound closed in the usual manner.

Dressings are applied, and the limb fixed on a back splint

with a foot-piece, side splints being used if considered requisite.

The limb must be kept on the splint until complete healing and union of the divided tissues has taken place.

Excision of the metatarso-phalangeal and interphalangeal joints.—Excision of these joints is performed through a single incision, or through double lateral incisions, placed a little nearer the dorsal than the plantar aspect of the sole (Fig. 360). The individual operations differ in no essential respects from the operations on the corresponding digits of the upper extremity (p. 511).

Excision of the temporo-maxillary joint.—The temporo-maxillary joint is formed by the glenoid cavity of the temporal bone and the condyle of the lower jaw.

Important anatomical structures lie in very close relation to the joint. The auriculo-temporal nerve and the superficial temporal artery lie posterior and external, the internal maxillary artery is below and internal, whilst the glenoid lobe of the parotid gland is situated immediately behind the condyle. The facial nerve lies in the parotid gland at a lower level.

FIG. 360.—Excision of metatarso-phalangeal and inter-phalangeal joints of great toe.

- a. Position of skin incision for metatarso-phalangeal joint.
- b. Position of skin incision for inter-phalangeal joint.

Indications.—Excision of the temporo-maxillary articulation may be necessary in tuberculosis of the joint, in some forms of osteo-arthritis, and in bony ankylosis from any cause.

Position.—The patient is placed in the dorsal posture, with the head turned towards the sound side, and supported by a pillow or sandbag. The surgeon stands on the affected side of the head and his assistant directly opposite to him.

Operation.—An incision about $1\frac{1}{2}$ in. in length is made along the inferior margin of the posterior part of the zygomatic arch, the skin being pulled upwards with the fingers of the left hand before the incision is made.

This incision commences immediately in front of the anterior margin of the external auditory meatus, and extends forwards towards the prominence of the malar bone (Fig. 361). The

skin, superficial fascia, and the deep fascia are divided, the auriculo-temporal nerve and the superficial temporal vessels being avoided in the posterior angle of the incision, and the temporal branch of the facial nerve in the anterior. In the anterior part of the incision the posterior margin of the masseter muscle will be exposed, and posteriorly the upper part of the parotid gland. The fibres of the masseter are retracted forwards (some of them being divided if requisite), and the parotid gland backwards. The external portion of the capsule of the joint is divided, and

FIG. 361.—Excision of temporo-maxillary articulation. Position of external incision.

the cavity opened. The neck of the lower jaw is next freed from the soft tissues, and with a fine saw it is divided from before backwards. The condyle is then seized with a pair of lion forceps, and forcibly pulled outwards. As this is being done, the undivided parts of the capsule are cut through with the scalpel, and the external pterygoid muscle is detached from the anterior and internal aspect of the neck immediately below the articular surface.

The head of the bone can now be removed. The interior of the joint is examined, and any diseased tissue removed.

All bleeding is then arrested, and the external wound closed by the insertion of sutures.

Excision of the temporo-maxillary articulation is in most instances a partial excision, the condyle being the only portion of bone which is taken away.

CHAPTER XXVII.

AMPUTATIONS AND DISARTICULATIONS.

By the terms amputation or disarticulation is understood the detachment and removal of a limb or part of a limb from the body.

The plane of section of the limb may either pass through a bone or bones, or through a joint; in the former case, the operation is usually designated an amputation, whilst to the latter the term disarticulation is often applied.

The term amputation is also applied by some surgeons to removal of the whole or part of the penis, the tongue, mammary gland, external auricle, and other dependent organs. It is better, however (with the possible exception of the penis and mammary gland), to restrict the term to removal by operation of a part or the whole of one of the upper or lower extremities.

Amputation or disarticulation of a limb should only be recommended in those cases in which it is impossible to save the limb or part of a limb by conservative and restorative measures, and at the same time leave a member which is of use to the patient. Aseptic and antiseptic surgery has, except in the case of patients suffering from malignant disease, so enlarged the field of conservative surgery, that amputations and disarticulations are much less frequently performed than was previously the case; and now it is considered a more creditable surgical performance to be able to save a diseased or injured limb than to remove it by an operation. When, however, malignant disease of a limb, either of the bone or soft parts, is under consideration, it must be remembered that conservative surgery does not offer the same advantages as regards saving the limb; but, on the other hand, it enables us with greater safety to remove the limb some distance above the seat of disease, and also to take away any lymphatic glands or groups of lymphatic glands which receive lymphatic vessels from the affected area. The mortality from operations involving removal of a limb or part of a limb, on

account of malignant disease, has been considerably reduced; and, owing to the more complete character of the actual procedure, in taking away all possibly diseased or infected areas, the patients are less liable to recurrence of the affection. It will be seen from these considerations that it is often a question of great difficulty to determine when to adopt conservative measures, and when and where to practise amputation or disarticulation.

Many injuries, which on a primary investigation appear to warrant amputation, when properly and scientifically treated by strict aseptic or antiseptic surgical methods, frequently heal; and, conversely, a certain number of small and slight injuries, which are treated by careless and inefficient aseptic or antiseptic methods, ultimately, owing to the development of severe complications, cause loss of the whole or a part of a limb, or even terminate fatally. Also, antiseptic surgery enables us to treat, by conservative methods, many of those complications which follow mechanical injuries to limbs, and which in former days were invariably regarded as necessitating amputation or disarticulation.

INDICATIONS FOR AMPUTATION.

A careful and scientific consideration of the "indications for amputation" involves a detailed and exact knowledge, in each individual case, of the character and extent of the pathological condition, disease, or injury which causes the question of the possible performance of an amputation to be brought forward. Thus it often happens, in order to justify a decision to amputate a limb or portion of a limb, that more than one surgical opinion is invoked. Whenever there is a doubt as to what line of treatment—conservative or amputation—ought to be recommended, it will usually be found advisable to allow the benefit of the doubt to incline towards conservative methods.

The following summary comprises most of the clinical conditions which may necessitate the performance of an amputation or disarticulation:—

(a) *Compound fractures of one or more bones of a limb, associated with extensive solutions of continuity in the main arterial, venous, and nerve trunks.*—Such injuries, when not treated by amputation, in almost all cases are followed at an early stage by the appearance of gangrene of that portion of the limb which lies at and beyond the seat of injury. When this occurs, an amputation is rendered imperative, and, when performed, is much more likely to give rise to septic complica-

tions which may prove fatal. On this account it is strongly recommended, when it has been decided that a limb ought to be removed on account of the severity and extent of the injuries, that the operation should be carried out as soon as possible after the reception of the injury. When there is much shock after the reception of an injury necessitating an amputation, the patient should be allowed to recover from this before commencing the amputation.

(b) *Extensive injuries to the soft parts of a limb.*—Certain cases of extensive injury to the skin and the soft tissues of a limb, such as, when the skin has been separated for the entire circumference of a segment of a limb, and the underlying fascial and muscular layers, together with some of the main arterial and nervous trunks, have been severely lacerated, can only be successfully treated by amputation. Some surgeons recommend, when dealing with conditions of this kind, that sufficient time should be allowed to elapse in order to determine where the line of demarcation will form, and, when this has become apparent, to then carry out an amputation on the proximal side of this line of demarcation. This, in my opinion, is a dangerous method to adopt, since, owing to the impossibility of making the injured tissues aseptic, putrefactive and septic processes establish themselves, and, when an operation is performed, especially when through the proximal portions of one of the extremities, they cause the death of a considerable number of patients, by extension of these septic processes to the field of operation. A class of injury of this kind which is occasionally met with is caused when a patient has been caught between a moving object, such as a train, and a solid body, such as a station platform. I have seen a number of patients who have slipped between a station platform and a moving train, and in whom the skin and underlying fascial tissues have been completely separated from the deeper structures, and the blood vessels torn and lacerated so extensively that it was necessary to at once perform an amputation. Often in these cases the injury to the superficial aspect of the skin has been insignificant.

(c) *Prolonged suppuration.*—Some cases of suppurative diseases of bone, such as septic osteomyelitis, may necessitate amputation when the septic process involves the bone and adjacent joints, and also when the fascial and intermuscular planes of the affected limb are infiltrated by the products of the pathological process. Amputation, however, in cases of this kind, should not be recommended until it is clear that conservative measures, such as free incisions, establishment of

free drainage, and the application of strong antiseptic solutions, have completely failed to arrest the progress of the disease. Tuberculous disease of a bone, owing to its intractability to local methods of treatment and its tendency to spread to adjacent tissues, occasionally requires treatment by amputation or disarticulation. The onset of amyloid disease is occasionally the determining point in deciding upon amputation.

(d) *Gangrene of a limb or portion of a limb from any cause.*—Gangrene in connection with a limb or part of a limb may be due to a variety of causes. Thus, in one class of patients, it is the direct or indirect result of the reception of an injury, in which cases it is often designated as “traumatic gangrene”; in another class it occurs in association with diabetes; in others, again, it is due to thrombosis of the large blood vessels which supply the affected limb; whilst, in others, senility and atheroma of the blood vessels appear to be the cause.

Whatever the cause of gangrene, the dead and useless tissues must be removed sooner or later. When the gangrene is of traumatic origin, and at the same time the tissues of the affected limb are the seat of septic processes, which are sufficiently severe to render possible or probable a fatal result, amputation should be performed as soon as possible. This is especially necessary when the gangrene is of the variety known as “acute traumatic.” When the gangrenous condition follows an injury, and there is no evidence of septic infection of the damaged tissues, or of the adjacent portions of the affected limb, it is usually advisable to wait until the line of demarcation between the dead and living tissues can be determined, since this forms a definite indication as to the exact site where the amputation ought to be performed.

Before coming to a definite decision as to the level at which an amputation should be performed, it is necessary to first select sound tissues through which to make the incisions; and, secondly, to ascertain that the main arterial trunks are permeable to the blood stream at the site where the operation is proposed to be carried out. This can usually be ascertained by paying attention to the temperature of the limb, state of sensibility of the skin, and the presence or absence of arterial pulsation in the tissues of the limb at the level of the plane of proposed section. When it is considered necessary to perform an amputation, in a patient who is the subject of diabetes, atheroma of the blood vessels, or Raynaud’s disease, owing to the development of gangrene, it will often be found advisable to perform the amputation a considerable distance above the gangrenous area,

on account of the defective circulation in the tissues immediately proximal to the diseased parts.

(e) *Chronic ulcers of the leg.*—Chronic ulcers of the leg,—non-malignant in character,—when they involve more than two-thirds of the circumference of the limb, usually necessitate amputation. In doubtful cases, it is strongly recommended that an attempt be made to render the diseased areas aseptic by the use of fomentations and antiseptic applications, and when this has been successfully done, to try, by plastic procedures and skin grafting, to cover the ulcerated areas with comparatively sound skin. If, however, the entire circumference of a limb is involved in an ulcerative process, then amputation should always be recommended, since plastic operations and skin grafting do not give rise to satisfactory results. Before coming to a definite decision in some of the cases of this class, it is necessary to take into consideration the position in life and the occupation of the patient, since, in people of means who have of necessity no physical labour to perform, it is often possible to preserve a limb in such a manner that it is quite a useful one; whilst if a patient's occupation necessitates much walking, and other physical exercise, then it is preferable that it should be removed and a suitable artificial one substituted.

(f) *Certain cases of congenitally deformed and useless limbs, old paralytic limbs, supernumerary digits, and atrophied limbs, which are useless to the patient, are a source of inconvenience, and cannot be improved by orthopædic measures.*—Whenever a limb is quite useless in the patient's economy, from one of the above enumerated causes, is a source of inconvenience to him, and there is no valid objection to the performance of a surgical operation, then the surgeon ought to recommend that an amputation of the useless member should be practised.

(g) *Sarcoma.*—Sarcoma of one of the bones of a limb in which the diagnosis is certain, is, in the majority of cases, best treated by amputation of the limb on the proximal side of the disease, and well above any infiltrated tissues. If the tumour be of the myeloid variety, local excision should first be practised, whilst a similar operation may be carried out in some of the slow growing and less malignant forms of fibro-sarcoma. Very careful observation, however, should be made of the patient for some time after the operation has been performed, since some forms of sarcoma, which at first appeared to be not very malignant, quickly recur and acquire more pronounced malignant characters. When a recurrence has taken place locally, amputation of the affected limb should at once be advised. The

longer the time which is allowed to elapse before amputation, the greater are the probabilities that secondary deposits will have commenced to form either in the lymphatic glands or in one or other of the internal viscera. Sarcoma of the periosteum, or of the medulla, when not of the myeloid variety, ought, as a general rule, to be treated by amputation of the limb on the proximal side of the affected bone. An exception may be made when the growth is located in the lower extremity of the femur. Then the level of the section of the bone is the lower part of the upper third. This is rendered advisable on account of the much greater mortality which follows disarticulation at the hip-joint, than when amputation is performed through the upper third of the femur, and also because it has been found, by clinical experience, that the percentage of recurrences is about the same whether the operation is through the hip-joint or through the upper part of the shaft of the femur. Sarcoma of the muscles or fasciæ of a limb usually justify an amputation at as early a period as possible, on account of their great proneness to recur if they are removed locally. To this there are certain exceptions, and each case must be carefully considered in all respects and decided on its individual characteristics.

(h) *Carcinoma*.—Carcinomatous affections of the skin of the extremities often necessitate amputation; but the extent of the disease as regards the amount of skin involved, and the subjacent tissues invaded, must guide the surgeon in coming to a decision. It will usually be found advisable to remove the lymphatic glands which receive the lymphatic vessels from the affected areas at the time of operation, in order to free the patient as far as possible from a recurrence. Secondary carcinoma, when it involves the bones or tissues of the extremities, does not call for amputation, on account of the impossibility of freeing the patient from all the manifestations and foci of the disease.

When an amputation or a disarticulation is performed immediately after the reception of an injury and on account of the effects of the injury, it is usually designated a "primary amputation or disarticulation." "Secondary amputation" is the term which is applied to an amputation when carried out some time after the reception of an injury, and necessitated by septic infection of the injured tissues, or the occurrence of gangrene. At the present time, secondary amputations are performed much less frequently than formerly, on account of the better results which have followed the antiseptic and aseptic treatment of injuries of the extremities.

POINTS TO WHICH PARTICULAR ATTENTION SHOULD
BE PAID IN AMPUTATIONS.

(a) *Determination of the site at which the limb or portion of limb is to be removed.*—It has often been stated by surgical authorities that, as a general rule, the value of a stump is greater in proportion to its length, and the further from the trunk the limb is removed the less is the risk to life from the operation, and hence that as much as possible of a limb should always be preserved. This statement requires considerable modification, since it ought to be the object of every surgeon who undertakes an amputation, to provide the most useful and painless stump possible, in order to enable the patient to use it without unnecessary pain and trouble, and to allow the surgical instrument-maker to fit a well-designed artificial substitute for the part which has been removed. It has been found by experience that a “conical stump” is the best for practical purposes, since it permits an artificial limb to be fitted in such a way that little or no pain results from wearing it. On this account it is strongly advised that all amputations above the ankle and wrist joints, especially the former, should be so designed and carried out as to provide the patient with a conical-shaped stump. The surgeon, however, in these endeavours to provide a useful and painless stump, must not leave tissues behind which are suspected, and which may probably be the seat of a recurrence of the disease. When coming to a decision concerning the seat of an amputation on the hand, in the region of the wrist-joint, it is necessary, in addition to providing a useful stump, to have regard to the physical appearance of the part. This is a point which especially requires careful consideration in ladies, and in persons whose position in life does not necessitate the retention of the most useful hand possible. Concerning the argument, that the further the plane of section of the limb from the trunk the less the risk to life, it can be definitely asserted that, since improved aseptic and antiseptic treatment of operation wounds has been adopted, this supposed danger is really non-existent, as the records of recent operations of this kind abundantly demonstrate.

(b) *The skin.*—Sufficient skin must, if possible, be retained to form a complete covering for the stump, without causing undue tension. The skin-flaps should be so arranged and fashioned that the resulting scar shall not lie over the end of the stump, or in a situation where it may be exposed to excessive or frequent pressure. Attention should also be paid, when deciding

upon the size and shape of the flaps, to ensure that they shall have an adequate blood supply. When making skin-flaps, therefore, the essential rules to follow are—first, that the flaps shall be of unequal length; and, secondly, that the bases shall have a wide attachment and an adequate blood supply.

In exceptional cases the rule, as regards providing a complete skin covering may be relaxed, since much may be done at a later period, by plastic operations, in restoring or completing the cutaneous covering of the terminal part of a limb.

(c) *The covering of the stump.*—The flaps should be so fashioned that plenty of fasciæ and muscle is left to form a good covering for the bone, and also to ensure an adequate blood supply to the flaps themselves. When the muscles of a limb are divided in an amputation, they retract towards the proximal end of the stump, and on this account due allowance must always be made for this tendency to retraction, otherwise it will happen that a surgeon is unable to cover the end of the limb with a suitable covering, and in order to satisfactorily effect this it becomes necessary to remove another segment of the bone and the adjacent tissues. When the incision through the soft parts has extended to the bone, the periosteum should be cut through in a circular manner, and then dissected upwards for half an inch or more according to the diameter of the bone at the level of section, so that, after the bone has been sawn through, the separated periosteum is sufficiently long to enable the surgeon to cover the cut surface of bone with it. Usually, after the periosteum has been separated in this manner, it is fixed over the cut end of the bone by the insertion of a few sutures. This method of dealing with the periosteum tends to prevent undue retraction of the muscles, provides a sufficient amount of soft tissues to cover the end of the bone, and assists in the formation of a conical stump.

After the periosteum has been fixed over the cut end of the bone, the divided extremities of the muscles should also be fixed to the deep fascial layers, and also to one another, by the insertion of a number of buried sutures, which in the majority of instances should be of strong catgut. This method of muscle-suturing diminishes the area of the wound, and hence the amount of secretion from its surface, forms a temporary fixation of the cut ends of muscle, which enables them to unite to the deep fascial layers, shortens the time occupied by the healing process, and helps in assuring a useful and painless stump. Fixation of the cut ends of muscle in this fashion also lessens the amount of severity of the post-operative pain, which is essentially due to irregular muscular contractions and twitchings.

In the case of a disarticulation, or amputation through a joint, if the nature of the case will permit, the capsular ligament is divided at the lower part of the articulation, and then brought over the end of the bone in a manner similar to that recommended above in the case of the periosteum.

(d) *The nerves*.—When dividing the soft tissues, an attempt should be made not to cut the nerves in such a manner that their extremities shall be so situated that they are liable to undue or frequent pressure.

The most frequent cause of painful stumps is either the development of a “neuroma or bulbous enlargement” of the divided end of one or more of the nerve trunks, or the involvement of one or more of these cut nerve-ends in the scar tissue of the stump. This unpleasant after-complication of an amputation operation can generally be avoided by dissecting out from the nerve sheath and removing about $1\frac{1}{2}$ in. or even more of each of the main nerve trunks on the proximal side.

(e) *The control and arrest of hæmorrhage and the prevention of unnecessary shock*.—At the time of operation the portion of the limb which it is desired to remove should be rendered “bloodless,” either by the application of a rubber bandage, as in Esmarch’s method, or by raising the limb for some minutes, and with the hands manipulating it so that the greater part of the blood within it is forced towards the trunk. When the tissues have been freed from blood by one of these methods, an elastic constrictor or tourniquet is placed around the proximal part of the limb in such a manner that it is not liable to slip during the operation, and when the muscles have been divided and retracted. A piece of aseptic lint is placed between the rubber constrictor and the skin. The tourniquet is applied sufficiently tightly to arrest the circulation of the blood in the large vessels. This method of operating minimises as much as possible loss of blood by the patient, and hence also diminishes the risk of the occurrence of severe shock.

In order to minimise shock in large amputations, some surgeons recommend intravenous injections of cocaine into the nerve trunks proximal to the site of amputation. The value of this method of treatment is somewhat uncertain.

METHODS OF AMPUTATION AND DISARTICULATION.

A considerable number of methods have been and still are made use of in the performance of amputations and disarticulations. A description of the most important ones will be given,

and indications pointed out as to which are the best to adopt in individual cases and in different parts of the limbs.

1. The circular method.—In this method the tissues of the limb are divided in a circular direction, that is to say, at right angles to the long axis of the limb that is being operated upon. The different tissues, however, are not all divided at the same level, the superficial structures being cut through more distally than the deeper ones. The operation wound, in an amputation performed by the circular method, has the form of a cone, the edge of the base of the cone corresponding to the cut margin of the skin and the apex to the bone (Fig. 362).

FIG. 362.—Diagrammatic representation of the stump of a limb when a circular amputation has been performed.

- a.* Skin and superficial fascia.
- b.* Deep fascia and superficial muscles.
- c.* Deep muscles.
- d.* Bone.

The skin and superficial fasciæ are first divided, and then retracted so as to expose the deep fascia at a slightly higher level. Next, the deep fascia is divided in a similar manner, and retracted. The superficial muscles are now cut through and allowed to retract, and then the deep muscles. After this the periosteum is incised and dissected back for a short distance, and finally the bone is sawn through. The periosteum should be separated sufficiently to entirely cover the sawn end of the bone.

When a circular amputation is being performed, where there are few soft tissues, the skin and superficial and deep fasciæ

are turned backwards in the form of a "cuff," so as to give more cutaneous covering for the stump.

One disadvantage of performing an amputation by the circular method is, that the scar is nearly always situated at the extremity of the stump, and is liable to injurious pressure and to form adhesions to the end of the bone.

2. The elliptical or oblique circular method.—The skin incision in this operation has the form of an ellipse, one extremity being nearer the proximal portion of the limb than the other (Fig. 363). The manner of division of the different tissues is exactly similar to that adopted in an ordinary circular amputation.

The elliptical method is a very good one, since the resulting

scar is situated not over the extremity of the stump, but a short distance proximal to it. A movable cutaneous covering for the stump is thus ensured.

3. The flap method.—In the performance of an amputation by this method, one or more flaps are fashioned from the soft tissues of the limb. These flaps may consist either of skin and fasciæ alone, or of skin, fasciæ, and muscle. In the latter case, the skin should always be cut longer than the muscles. It is better, in the majority of instances, that an amputation flap should contain muscle at its base, and not consist throughout of skin and fasciæ alone.

Varieties of the flap method—(a) *Single flap.*—The single flap may consist of either skin and fascia, or of skin, fascia, and muscle, and may be formed from the tissues on any aspect of the limb. Its width should be equal to half the circumference of the limb at the level at which the bone is to be sawn.

(b) *Two flaps.*—When two flaps are formed, they may either be of equal length, or one may be longer than the other. It is generally preferable that the flaps should be of unequal length, so that the resulting scar

FIG. 363.—Method of making an elliptical or oblique circular incision.

FIG. 364.—Forms of amputation flaps.

- a. Single flap.
- b. Equal antero-posterior flaps.
- c. Equal lateral flaps.
- d. Unequal antero-posterior flaps.
- e. Unequal lateral flaps.

may not be situated over the extremity of the stump. The flaps may either be antero-posterior or lateral.

When the flaps have square-cut extremities, they are called

“rectangular” flaps; when the angles are rounded off, “U-shaped.” The latter (U-shaped flaps) will generally be found more convenient, and will give a better-shaped stump than rectangular ones.

The best method for the formation of flaps in amputations is that which comprises the fashioning of two cutaneo-fascial flaps, one longer than the other, each U-shaped, and consisting of skin, superficial fascia, and subcutaneous tissues, and the deep fascia. When the two flaps are of unequal length, the line of union and subsequent scar are away from the end of the bone, and conse-

quently in such a position as to conduce to a useful and painless stump.

4. The modified circular method.—In the modified circular method of amputation, a circular incision is first made through the skin and fascia; then one or two lateral incisions are made, which extend proximally for a short distance. If two lateral incisions are made, we have two short flaps which may be rectangular in shape or have the corners rounded off. The flaps in all cases are of equal length, and are composed of skin

FIG. 365.—Modified circular incision.

FIG. 366.—Modified elliptical or “racket-shaped” incision.

and superficial and deep fasciæ. The further stages of the operation are similar to those in the circular method (Fig. 365).

5. The modified elliptical or “racket-shaped” method.—This form of amputation is a modification of the elliptical method, the incision being prolonged up the limb from the proximal extremity of the ellipse (Fig. 366).

MODES OF FASHIONING FLAPS.

Three distinct modes of fashioning flaps are practised, but in my opinion the one which is first described is that which fulfils all ordinary operative requirements, and ought therefore to be adopted in almost every case.

(a) *By cutting from without inwards.*—Nearly all amputation

flaps should be made by cutting from without inwards, and never in the converse direction from within outwards. When a flap is fashioned by this method, an incision is made through the skin and superficial fascia, marking out the size and shape of the flap. These tissues are retracted for a very short distance, and then the deep fascia is cut through. The flap, thus commenced, is dissected upwards for a variable distance, according to the case which is being operated upon, and then the muscles are cut until the periosteum of the bone is reached. This latter is cut through, either in a circular manner, or a flap is fashioned, and separated from its connections with the bone for a sufficient distance, so that, when the section has been made through the bone, this cuff or flap of periosteum will form a complete covering for the end of the bone. For this method of making amputation flaps, it is advisable to use a knife with a moderately short and stout blade. Fig. 396 illustrates a knife of suitable form.

(b) *By transfixion*.—In this case a knife whose blade is equal in length to at least half the circumference of the limb, is used. The first incision transfixes the limb from side to side. Thus, in amputation of the forearm by this method, the knife is entered on one side, passes down to the bone, then across the limb in front of the bones until its point emerges on the opposite side, half-way round the limb. By a sawing movement the tissues are divided in a distal direction for the necessary distance. The edge of the knife is then turned towards the surface, and a cut is made outwards in such a manner that the skin is left longer than the muscles. The knife is then passed behind the bones, and the posterior flap made in a similar manner.

This practice of fashioning flaps by the “transfixion method” has almost entirely been discontinued, and rightly so, on account of the long and large instruments which are necessary for its performance, the large sterilisers which must be available for their efficient sterilisation, and also on account of the possibility of slitting the large blood vessels for the entire length of the wound.

(c) *By dissection*.—This mode of forming an amputation flap is only occasionally employed. The shape of the flap is first marked out by making an incision in the skin and superficial fascia. These structures are retracted for a short distance, and then the muscles are divided and dissected up from the bone, so that the muscular flap has the shape of the original skin incision.

Size of flaps.—The two flaps together have to cover the raw surface of the limb at the place of section, and hence must correspond with this in size, due allowance being made for retraction by the divided muscles. Two points must therefore be kept constantly in view—(1) That shrinkage in the flap always occurs immediately after division of the muscular strata and also at a later period; and (2) that full allowance for this shrinkage must always be made. A general rule, which may be adopted as regards the length of amputation flaps, is that the length of the two flaps together should be equal to one and a half times the diameter of the limb at the level of the plane of section of the bone (in the thigh they should be a little longer than this), and that in width they should each be half the circumference of the limb at the same level.

The question of contractility of flaps in amputations is of especial importance to the surgeon who has gained most of his experience in the performance of amputations in one or more courses of operative surgery on the dead body. On this account, experience which has been gained by operations upon dead material must be modified when a student commences to operate on the living tissues, in which the elastic and muscular tissues invariably contract or retract when they have been divided with the scalpel. When performing an operation upon the living subject for the first time, a student should take precautions to ensure that the flaps when fashioned are sufficiently long to cover the end of the stump after retraction has taken place, and to rather err in making them too long than too short. If it should so happen that they are too long, it is an easy matter to remedy this defect, whereas, if they are too short, a reamputation has to be performed either then or at a later period.

Position of operator and assistant.—In all operations on the extremities above the wrist and ankle respectively, except in disarticulation at the left hip-joint, and in removal of the upper extremity, the operator should stand on the outside of the affected limb on the right side of the body, and inside on the left. His assistant in all cases should stand on the opposite side, somewhat nearer the trunk.

When possible, in amputation operations, it will be found advisable for the operator to grasp the limb at the seat of proposed section of the bone with his left hand, so as to form a ready guide to the eye whilst fashioning the flaps.

Instruments for amputation or disarticulation.—Any amputation or disarticulation can be performed with a small

number of instruments, the only special ones being a saw of suitable size and shape, according to the part which is to be removed, a pair of bone forceps, and a periosteal elevator. An elastic constrictor or tourniquet should always be at hand, in order to control the circulation when necessary.

AMPUTATIONS AND DISARTICULATIONS IN THE UPPER EXTREMITY.

Removal of digits.—*General considerations.*—The removal by operation of a portion of the upper extremity, especially a portion of the hand, must only be carried out after the most careful consideration by the operator of the best possible functional result which may be obtainable. The prehensile and grasping functions of the fingers and hand must never be lost sight of in the treatment of injuries and inflammatory and suppurative affections of these parts. Conservative and restorative surgery here finds the greatest scope for its intelligent practice, and on this account it is in the hand that the greatest number of irregular and atypical operations are performed. None of the artificial substitutes which are made to replace a hand are of the same prehensile and grasping powers, and therefore it behoves the surgeon to save as much as is possible of the different parts of the hand. This remark applies with especial force to the treatment of injuries and diseases of the thumb, since this digit is of the utmost importance in carrying out the prehensile and grasping functions.

As a general rule, it may be asserted that the skin on the palmar aspects of the digits is the most suitable for forming a flap-covering to an amputation wound, on account of its extensive vascular and nervous supply; therefore, other circumstances being equal, it is strongly advised that the surgeon should, as far as is feasible, utilise as often as possible the tissues from this aspect when fashioning flaps. When, however, unnecessary or even harmful shortening of a mutilated or diseased digit can be partially or completely prevented by obtaining flaps from the lateral or dorsal aspects, then in every instance of this kind the surgeon should not hesitate to modify his proceedings so as to obtain the best functional result. As regards removal of a portion of the nerves which supply a digit, this is not possible in the same way as in the more proximal parts of the extremity where the nerve trunks are of much larger calibre, and can readily be seen without carrying out a careful dissection. Special attention is not directed to this

point, on account of the difficulties in carrying it out, and also of the unnecessary and harmful injury which is inflicted on the tissues of the flaps.

In order to obtain the best functional result, it is advised, after removal of a portion of a digit, whether through one of the phalanges or either of the interphalangeal joints, that the flexor and extensor tendons should be united together, over the end of the bone, by a few points of suture, and also fixed in a similar manner to the periosteum of the adjacent portion of the phalanx.

When a disarticulation of a digit is performed at a metacarpophalangeal joint, the head of the metacarpal bone should be left in every case where it is important and desirable that the best possible functional result should be obtained. When, however,

the appearance of the hand is considered to be of more importance than the retention of its functions, as is often the case when dealing with ladies or men of wealth, then the head of the metacarpal bone and the adjacent portion of the shaft should be removed.

A finger may be amputated through the second interphalangeal joint, the first interphalangeal joint, or the metacarpophalangeal joint; or one of the phalanges may be divided, or the entire digit may be taken away together with its metacarpal bone.

Anatomical considerations.—*Position of the joints.*—When the digits are partially flexed, three prominences are apparent on their dorsal aspect in the neighbourhood of the metacarpophalangeal and interphalangeal joints. In each case the joint lies distal to the prominence, this being formed by the head of the metacarpal bone or phalanx. The metacarpophalangeal

joint is situated about one-third of an inch distal to the prominence of the knuckle; the first interphalangeal joint one-fifth or one-sixth of an inch beyond the prominence formed by the distal extremity of the first phalanx, and the second interphalangeal joint about one-tenth of an inch distal to the prominence formed by the head of the second phalanx. On the palmar aspect of the digits three transverse furrows are visible, the proximal one two-thirds of an inch distal to the plane of the metacarpo-phalangeal joint, the middle one directly opposite the first interphalangeal joint, and the third or distal crease about a quarter of an inch proximal to the line of the corresponding joint.

Ligaments. — The strong ligaments of the metacarpo-phalangeal and interphalangeal joints are the two lateral ones. The palmar ligament is of medium thickness, whilst on the dorsal aspect the aponeurosis of the extensor tendon takes the place of a ligament.

Insertion of tendons. — The tendons of the flexor profundus digitorum are inserted

into the palmar aspect of the bases of the distal phalanges; those of the flexor sublimis digitorum into the lateral aspects of the shafts of the second phalanges; the slips from the interossei and lumbricales into the lateral aspects of the bases of the first phalanges; and the extensor communis digitorum into the dorsal aspect of the bases of the second and third phalanges (Fig. 367).

FIG. 368.—Finger and thumb, showing position of skin incisions in amputation of distal phalanx by a long palmar flap.

Sheath of the flexor tendons.—On the palmar aspect of the first and second phalanges there is a well-marked fibrous canal, lined by a synovial sheath, and containing the flexor tendons.

Amputation through the distal interphalangeal joint.—The following varieties of operation have been made use of :—

(a) Long palmar flap.

(b) Long palmar and short dorsal flaps.

Special instruments.—Narrow-bladed scalpel and short finger-knife, and the ordinary instruments for an amputation.

Position.—The hand is pronated, and the adjacent fingers held aside by two strips of aseptic gauze by an assistant. The surgeon stands or sits facing the limb.

Operation.—(a) *By a long palmar flap.*—The phalanx to be removed is firmly grasped by the left hand of the surgeon, and the second interphalangeal joint flexed. A transverse incision is made across the dorsal aspect of the joint, extending half-way round the digit. This incision should open the joint. The

FIG. 369.—Finger from which the terminal phalanx has been removed, showing a long palmar flap.

lateral ligaments are divided, and the edge of the knife, after cutting through the palmar ligament, is turned towards the tip of the finger, and then, by a slight sawing movement, a flap is cut. Care must be taken to make the extremity of the flap almost square, so as to correspond with the dorsal incision. It usually comprises about two-thirds of the pulp of the finger.

Any bleeding vessels present are ligatured, and then the flap is turned over the free extremity of the second phalanx and stitched to the margins of the dorsal incision.

If a narrow-bladed knife is not available, the palmar flap may be dissected up first with the scalpel, and disarticulation performed from the dorsal aspect as before.

(b) *By a short dorsal and a long palmar flap.*—In this case a short dorsal flap, one-third the length of the palmar, is dissected up before opening the joint. The other stages of the operation are similar to the preceding, with the exception that the palmar flap is correspondingly shorter.

Amputation through the second phalanx of a finger.—

Whenever possible, the amputation should be performed through the distal third of this phalanx, in order to preserve the insertions of the tendon of the flexor sublimis digitorum. Whether this is practicable or not, the divided extremities of the extensor and flexor tendons should be sewn together over the distal extremity of the first phalanx, so as to render movements of the remaining portion of the digit as useful as possible.

The amputation may be performed by the following methods :—

- (a) Long palmar flap.
- (b) Short dorsal and long palmar flaps.
- (c) Equal antero-posterior flaps.
- (d) One long lateral flap.
- (e) Two unequal lateral flaps.
- (f) Equal lateral flaps.

The first two of these methods are the best, and should be adopted whenever the condition of the part will allow.

(a) *By a long palmar flap.*
—The hand being held as in the previous operation, the operator decides upon the level at which he will divide the bone. An incision is then made round half the circumference of the digit on its dorsal aspect, at the level of the proposed plane of section of the bone. The point of the knife is then entered at one extremity of this incision, passed transversely across on the flexor aspect of the phalanx, emerging at the opposite side of the digit. By a series of sawing movements, a palmar flap, two-thirds to three-quarters of an inch, is made, and the edge of the knife then turned towards the palmar surface, and made to cut its way outwards. The soft parts are retracted for a short distance, the periosteum divided, the section of the bone made with a finger saw, and the distal portion of the digit removed.

FIG. 370.—Amputation of a finger through second phalanx.

- a. By long palmar flap.
- b. By unequal lateral flaps.
- c. By equal lateral flaps.
- d. By a single long lateral flap.

Hæmorrhage is arrested, the divided tendons united and fixed to the periosteum, and the flap is then turned over the end of the finger and sutured in position.

(b) *By a short dorsal and a long palmar flap.*—A short dorsal flap, one-third the length of the palmar one, is dissected up, and then the palmar flap is fashioned as in the preceding case, but cut somewhat shorter. The further stages of the operation are similar to the preceding.

(c) *By equal antero-posterior flaps.*—The plane of section of the bone having been determined, an incision is made commencing at the lateral aspect of the finger, passing downwards for half or three-quarters of an inch, then transversely across the dorsum, and upwards on the opposite side. The flap so marked out is dissected upwards, and a similar flap made on the palmar surface. The flaps are retracted, the tendons cut across, the periosteum divided, and the bone sawn through.

Hæmorrhage is arrested, the tendons united together and fixed to the periosteum, and the margins of the flaps united with sutures.

(d) *By one long lateral flap.*—The plane of section of the bone having been decided upon, a vertical incision is made along the middle line of the dorsal aspect of the finger, commencing at this level and extending downwards for three-quarters of an inch. The incision is carried round to the palmar aspect of the finger, and then upwards along the middle line on the palmar surface to a point opposite that at which it commenced. The flap, consisting of skin and fascia, is dissected up to the plane of section. Then with the scalpel the soft tissues on the opposite side of the finger are divided transversely, together with the flexor and extensor tendons, and the bone sawn through.

Hæmorrhage is arrested, the divided tendons sutured together over the end of the bone and fixed to the periosteum, and finally the flap is adjusted over the end of the finger and fixed in position by sutures.

(e) *By two unequal lateral flaps.*—The details of this operation are similar to those of the preceding, with the exception that a short flap is dissected back on one side and a longer one on the other.

(f) *By equal lateral flaps.*—The incision in this operation is similar to that in the preceding, but it is carried for a shorter distance along the dorsal aspect of the finger, and two flaps of equal length are cut.

Amputation through the proximal interphalangeal joint.

—The best operation for this purpose is that in which a long palmar and a short dorsal flap are made.

Operation.—The level of the joint being defined, a short dorsal flap, one-third of an inch in length, is dissected back. The joint is then opened from above, and the palmar flap, two-thirds of an inch in length, formed by cutting distally behind the phalanx.

Hæmorrhage is arrested, the extensor tendon on the dorsal aspect of the phalanx, and the flexor tendons on the palmar aspect, brought over the end of the phalanx, joined together, and fixed in position with sutures. The palmar flap is then adjusted to the dorsal one, and the margins united in the usual manner.

Amputation of a finger through the metacarpophalangeal joint.

—This is usually done by means of a “racket-shaped” incision. The finger which is to be removed being firmly grasped by the left hand of the surgeon, and the adjacent fingers being held aside with strips of aseptic gauze by an assistant, the incision is commenced over the middle line of the dorsal aspect of the corresponding metacarpal bone, one-third of an inch from

FIG. 371.—Position and shape of incision in amputation of a finger through the metacarpophalangeal joint.

- a. Without removal of head of corresponding metacarpal bone.
- b. With removal of head of metacarpal bone.
- c. Index finger.
- d. Little finger.

its distal extremity. It is continued downwards to the level of the joint, and then round one side of the finger across the palmar aspect just beyond the web, and up the other side till it reaches the vertical incision again. The flap having been dissected up on each side, the extensor tendon is divided, and disarticulation is performed from above. Any bleeding

digital arteries are ligatured, the flexor and exterior tendons anchored by sutures to the periosteum, and the two flaps are brought over the convex extremity of the metacarpal bone and fixed by the insertion of sutures.

If the patient belongs to the upper classes, and the appearance of the hand is of more importance than the utility for physical labour, the head of the metacarpal bone should be removed.

This is effected by dissecting back the tissues covering it for a short distance, cutting through the transverse metacarpal ligament, and then dividing the shaft with a fine metacarpal saw. Bone forceps should not be used for this purpose, since they are liable to cause splintering of the bone. The later stages of the operation are as before.

Amputation of a finger together with its metacarpal bone.—The plane of the carpo-metacarpal joint having been determined, an incision is made along the dorsal aspect of the metacarpal bone for its proximal two-thirds, and then round the finger just beyond the web in an oval manner, as in the preceding operation. The flaps are dissected away

FIG. 372.—Amputation of a finger with the corresponding metacarpal bone.

- a. Position of incision for third finger.
- b. For index finger.
- c. Fifth finger.

from the bone, the dorsal interosseous muscles being detached, and then with the point of the knife the carpo-metacarpal ligaments are cut through. Care must be taken in this part of the operation not to allow the point of the knife to travel into the tissues of the palm, in which case severe hæmorrhage might ensue. When disarticulation has been performed, the base of the bone is raised, the soft tissues on its palmar aspect separated, and the digit removed.

All bleeding vessels having been ligatured, the margins of the wound are brought together and fixed by the insertion of sutures.

In removal of the little finger with its metacarpal bone, the incision is made along the ulnar side and not on the dorsal aspect.

Amputation of the thumb at the carpo-metacarpal joint.

—The distal part of the thumb being held by the left hand of the surgeon, an incision is made which commences over the base of the metacarpal bone on the radial side. This extends downwards to a point a short distance above the head of the bone, then obliquely round the dorsal and ulnar aspects of the first phalanx until the middle of the palmar aspect is reached. The incision is then continued round the thumb on its radial

FIG. 373.—Removal of thumb at carpo-metacarpal joint.

a. Position of skin incision.

side, until it joins the first part of the incision on the proximal side of the head of the metacarpal bone. With the scalpel two flaps are now dissected up from the tissues of the thenar eminence and the ulnar side of the thumb and its metacarpal bone, until the bones are exposed and separated from their immediate muscular and fascial connections. Disarticulation is performed from the dorsal aspect of the joint, care being taken to avoid the radial artery as it dips in between the two heads of the first dorsal interosseous muscle at the base of the first inter-metacarpal space.

For the performance of this operation, transfixion of the thenar eminence has been recommended, but in my opinion is not necessary. Section of the soft tissues is readily and effectively carried out by the procedure described.

When the thumb has been removed in this manner, all bleed-

ing vessels are seized with forceps and ligatured. Finally, the flaps are coapted together and fixed by the insertion of sutures.

Whenever possible a portion of the metacarpal bone of the thumb should be left, for the reasons which have already been discussed (p. 539).

Amputation at the wrist-joint.—The general rules to be observed in the performance of an amputation through the neighbourhood of the wrist are, that as much as possible of the limb should be preserved, the inferior radio-ulnar joint should not be opened, and the covering for the extremities of the bones should be derived chiefly from the tissues of the palm.

FIG. 374.—Amputation at the wrist by long palmar and short dorsal flaps. The dark line represents the palmar flap, and the dotted line the dorsal one.

Indications.—(a) Extensive tuberculous affections of the wrist, together with other chronic inflammatory conditions of the carpus which cannot be satisfactorily treated by excision; (b) severe injuries which cause destruction of the distal part of the hand; (c) occasional cases of contraction of the hand following burns.

The best form of amputation through the wrist-joint is by a long palmar and a short dorsal flap.

Other methods are by equal antero-posterior flaps, by a long external lateral flap, and by the circular method.

(a) *By a long palmar and a short dorsal flap.*—*Position.*—The patient is placed in the dorsal position, with the arm at right angles to the side, the forearm supinated, and the hand resting on a small table. The surgeon stands or sits opposite the end of the limb and the assistant opposite to him. A second assistant controls the circulation in the brachial artery, either by digital pressure or by applying some form of tourniquet.

Operation.—The surgeon grasps the fingers with his left

hand, an assistant abducts the thumb, the wrist is extended, and the positions of the styloid processes of the radius and ulna defined. An incision is then made, commencing at the styloid process of the radius, passing vertically downwards over the thenar eminence to the middle of the palm, then transversely across the palm, and upwards over the hypothenar eminence to the styloid process of the ulna. The free extremity of this flap should be slightly convex. The flap is dissected up, and made to include the deep palmar fascia, and if possible the superficial palmar arch as well as in its upper part, portions of the muscles of the thenar and hypothenar eminences, so as to preserve a good blood supply to the part (superficialis volæ and superficial branch of the ulnar artery).

The hand is now pronated and strongly flexed at the wrist, and a dorsal incision made from the styloid process of the ulna to that of the radius, across the dorsum of the wrist a short distance below the line of the joint. The extensor tendons being cut through, the wrist is further flexed, and the lateral ligaments of the radio-carpal joint are divided; and then, with a few strokes of the knife across the dorsal aspect of the wrist, the remaining ligaments are cut through, and the hand finally detached by division of the flexor tendons.

FIG. 375.—Amputation at the wrist by equal dorsi-palmar flaps.

- a. Dorsal incision.
- b. Palmar incision.

The distal extremity of the radius, the interarticular fibro-cartilage attached to the lower end of the ulna, and the inferior radio-ulnar joint, are now examined, and if there are any traces of disease, this is removed by scraping with a sharp spoon, or, if the disease is extensive, the articular surfaces of both bones may be sawn off. If this is necessary, however, the movements of pronation and supination are very seriously interfered with.

In all cases the apices of the radial and ulnar styloid processes should be removed.

The compression of the brachial artery is now relaxed, so as to render evident the arteries which have been divided. These are picked up with artery forceps and ligatured. The principal vessels requiring ligature are the radial branches of the ulnar, the superficialis volæ, and the terminal branches of the anterior and posterior interosseous. The divided extensor and flexor tendons are now either joined together over the ends of the bones, or are fixed by sutures to the periosteum which covers the ends of the bones. When this has been done, the cutaneo-fascial flaps are carefully sutured.

FIG. 376. — Amputation of the wrist by a long external lateral flap. Position of skin incision.

(b) *By equal anterior and posterior flaps.*—This operation may be performed when the condition of the skin of the palm does not allow of the previous operation being carried out. The details of the operation are similar to the preceding, with the exception that the two flaps are made of equal length (Fig. 375).

(c) *By a long external lateral flap.*—This method of operating should only be made use of when all the tissues of the ulnar side of the hand are extensively diseased or injured, and the distal part of the thumb is also rendered useless.

Operation. — An incision is made which commences on the dorsal aspect of the wrist, somewhat nearer to the radial than the ulnar side, passes first downwards, then outwards, crossing the metacarpal bone of the thumb just below its head, then upwards over the thenar eminence, terminating at a point in front of the wrist corresponding to the point of commencement on the dorsum. A horizontal incision is next made at the level of the wrist-joint, commencing at the dorsal extremity of the first incision, extending round the ulnar side, just below the styloid process of the ulna, and ending at the palmar extremity of the primary incision. The flap which has been outlined on the outer side is dissected up, care being taken to include in it some of the muscles of the thenar eminence. The flap is well retracted,

the flexor and extensor tendons divided, and disarticulation performed, the joint being opened from the outer side.

The bones, the bleeding vessels, and the divided tendons are treated as in the preceding operation, and finally the flap is brought over the extremities of the radius and ulna, and fixed in position by the insertion of sutures.

(d) *By the circular method.*—The skin of the forearm is drawn well upwards by the assistant, and a circular incision made through skin and superficial fascia at the level of the carpo-metacarpal joints. This will include the proximal parts of the thenar and hypothenar eminences. The skin is then further retracted or dissected backwards in the form of a cuff, and the deep fascia and the underlying tendons cut through. These structures are retracted for a short distance, and then the wrist-joint is opened, and the hand removed.

The vessels are secured, the bones and divided extensor and flexor tendons treated as before, and then the soft parts are drawn over the extremity of the limb and fixed by the insertion of sutures.

Amputation through the forearm.—An amputation through the forearm may be performed in the following ways:—(a) By unequal skin-flaps, longer dorsal and shorter palmar, with circular division of the muscles; (b) by lateral flaps; (c) by the circular method. This last mode of operation is most suitable for amputation through the lower third of the forearm; it cannot be satisfactorily practised in the upper part.

In the majority of instances when performing amputations through the forearm, and disarticulation at the elbow-joint, the best results and the most satisfactory stumps can be obtained by adopting the method of “antero-posterior” cutaneo-fascial flaps with deeper division of muscles, the flaps being of unequal length. There is not much to choose between a long anterior and a short posterior flap and the reverse, although, in my opinion, a more satisfactory stump is obtained by making the long flap anterior. Often, however, owing to the nature of the disease or injury, and the parts of the forearm which are most extensively involved, better results can be gained by making lateral unequal flaps; and when this is the case, the surgeon should not hesitate to adopt one of these methods in preference to the antero-posterior one. An important factor in ensuring a movable stump is careful suturing of the periosteum and flexor and extensor tendons, as already recommended and described.

(a) *Amputation through the forearm by antero-posterior flaps.*—The limb is prepared in the usual manner for an amputation,

and an Esmarch's tourniquet is applied to the lower third of the upper arm, in order to compress the brachial artery and control hæmorrhage.

Special instruments.—The most suitable knife is a small amputating knife, with a blade 3 or 4 in. in length. The saw is the usual amputation saw.

Position.—The affected limb is fully extended, with the forearm pronated and held by an assistant. The surgeon stands on the radial side of the limb in the case of the right arm, and on the ulnar side in the case of the left. His assistant stands opposite to him.

Operation.—The plane of section of the bones having been decided upon, the surgeon grasps the forearm with the left index finger and thumb at this level. With the knife an incision is

FIG. 377.—Amputation of the forearm by antero-posterior flaps.

a. Line of anterior incision.
b. Line of posterior incision.

made, which commences at the level of the plane of section and passes vertically downwards for $2\frac{1}{2}$ or $3\frac{1}{2}$ in., according to the size of the limb, and then transversely across the extensor aspect to a point on the ulnar side half-way round the limb, the end of the flap being made slightly convex. The incision is completed by continuing it along the ulnar margin of the limb to the level of the plane of section of the bones. The flap thus marked out is dissected up by a series of light strokes with the knife; it should consist of skin, superficial and deep fascia, and at its base of some muscle. When the flap has been dissected up, it is retracted by the assistant, and the hand is supinated.

The second flap, which should be from $1\frac{1}{2}$ to $2\frac{1}{2}$ in. in length, is formed on the palmar aspect of the limb by sweeping the knife from the ulnar to the radial side in a slightly curved direction, so as to give its extremity a broadly convex outline.

It is dissected up in a manner similar to the preceding, and then both flaps are fully retracted by the assistant.

The muscles are next divided by a series of circular cuts down to the bone, the periosteum is cut through at a point two-thirds of an inch above the level at which the saw is to be applied, and separated upwards for this distance with a periosteal elevator. The bones are then sawn across. In doing this, care must be taken not to cause splintering. This is avoided by the assistant holding the limb steady, and the surgeon sawing with a series of light sweeps. The forearm should be fully supinated while the bones are being sawn.

The blood vessels, of which there are four main ones,—radial, ulnar, and anterior and posterior interosseous,—are sought for and ligatured. The radial lies under cover of the supinator longus in close proximity to the radius. The ulnar lies beneath the flexor carpi ulnaris, anterior to the ulna. The anterior interosseous lies on the anterior aspect of the interosseous membrane. The posterior interosseous in the upper part of its course lies between the superficial and deep layers of muscles, whilst in the lower third of the forearm it is generally on the interosseous membrane.

The “cuffs” or flaps of periosteum are sutured over the ends of the bones.

Any tags of tendon which may appear on the surface of the wound are cut away, if necessary, and the cut ends of the flexor and extensor tendons united by sutures or fixed to the periosteum. The flaps are next brought over the ends of the bones and fixed together by the insertion of sutures.

(b) *By lateral flaps.*—In performing an amputation through the forearm by the lateral flap method, the incisions are made in a vertical direction along the dorsal and palmar aspects of the limb. In other respects the operation is similar to that above described.

Some surgeons recommend that the flaps should be formed by transfixion, but this method presents no advantage over the one detailed above, and moreover the flaps cannot be shaped with such great accuracy.

(c) *By the circular method.*—This operation is only suitable for an amputation through the lower third of the forearm.

Position.—The limb is extended and abducted, the forearm supinated, and the hand held by an assistant. The surgeon stands on the radial side when operating upon the right limb, and on the ulnar side when operating upon the left.

Operation.—The level of the section of the bone having been

marked out, the left hand of the surgeon retracts the skin upwards. Then the knife is passed round the limb from below, and a circular incision is made 2 to 2½ in. distal to the plane of section. This incision divides the skin, superficial and deep fasciæ, and then these tissues are dissected upwards as far as the level at which the bones are to be sawn. It is usually con-

venient to turn them back in the form of a cuff. A second circular incision is now made through all the remaining soft tissues down to the bones, the muscles being allowed to retract, and the periosteum divided at a slightly higher level. The periosteum is separated from the bones for about half an inch, and then the bones are sawn across. The blood vessels are ligatured, the periosteum and tendons fixed by sutures, and the

soft parts drawn over the end of the stump and sutured in the usual manner.

Amputation through the elbow-joint.—This may be performed by the following methods:—(a) By antero-posterior flaps; (b) by unequal lateral flaps; (c) by the elliptical method; (d) by the circular method. The best methods of amputating through the elbow-joint are by a long anterior and short posterior flap, and by the elliptical method. Both these operations provide a thick muscular covering, well supplied with blood vessels, for the end of the humerus.

The circular method is easy in its performance, and gives a small wound, but does not afford such a good covering for the end of the bone, while the scar is left in an exposed situation.

The anterior and lateral aspects of the lower extremity of the humerus are well covered with muscles, the posterior aspect being more superficial. The internal condyle is situated at a lower level than the external, and is more prominent. This must be borne in mind when disarticulating.

(a) *By a long anterior and a short posterior flap.*—The skin is rendered aseptic, and hæmorrhage is controlled by the application of an Esmarch's elastic tourniquet to the middle of the upper arm.

Position.—The limb is somewhat abducted from the side, and held by an assistant in a position of complete supination, with the elbow slightly flexed. The operator stands on the radial side of the right limb, and on the ulnar side of the left limb.

Operation.—The positions of the internal and external condyles of the humerus are determined, and a point selected 1 in. below the internal, and another $1\frac{1}{2}$ in. below the external. With a short amputation knife an incision is made which commences at the first point (in the case of the right limb), extends downwards along the ulnar margin for 3 in., then almost transversely across the front of the forearm, and upwards on the radial side to the point $1\frac{1}{2}$ in. below the external condyle.

The extremity of the flap is cut somewhat convexly, and then dissected upwards. The flap at first consists of the skin and fasciæ, and then of muscle as well.

The margins of the first incision are joined across the posterior aspect of the limb by making a cut from one side to the other in such a manner that a flap about one-third the length of the anterior is fashioned. This is dissected back to its base, and then both flaps are well retracted by the assistant. Any remaining muscles or other soft tissues in front of the joint are now divided. The joint is opened on the outer side, the ligaments

cut through, and disarticulation completed by cutting out behind. The tendon of the triceps is the last part to be divided. The brachial artery is secured as it lies in front and at the inner side of the stump, the elastic tourniquet is relaxed, and the various small vessels of the arterial anastomosis about the elbow-joint picked up with artery forceps, and ligatured. The main nerve trunks are dissected free for 1 in. above the plane of section of the limb, cut through and removed. The flaps are then brought into apposition and fixed by the insertion of sutures, after uniting the divided muscles and tendons with several points of suture over the end of the bone and fixing them to the ligaments.

It is usually advisable to leave open one angle of the wound, so as to provide for the escape of secretion from the remaining part of the synovial membrane of the joint.

(b) *By unequal lateral flaps.*—If this method is employed,

FIG. 379.—Amputation at the elbow-joint. By an elliptical incision.

a. Position of anterior part of incision.

b. Position of posterior part of incision.

the incision is made from the front of the elbow-joint, terminating behind the olecranon. The long flap may be either external or internal, according to the state of the tissues at the time of operation.

(c) *By the elliptical method.*—The proximal extremity of the ellipse should be situated on the extensor aspect of the limb, immediately above the upper border of the olecranon process of the ulna, and the distal extremity on the flexor aspect of the forearm, just below the junction of the upper with the middle third.

An incision is made which marks out the ellipse, commencing above and behind, extending downwards to the lowest point in front, and then upwards again to the olecranon behind. As the surgeon makes this incision, the limb, which is held by an assistant, is rotated so as to expose the parts which are being cut. The skin and fasciæ are retracted and dissected up for a

short distance, and then the soft tissues in front of the elbow-joint are divided with the knife, so as to form a muscular anterior flap. This flap is retracted by an assistant, and the remaining soft tissues divided until the anterior aspect of the elbow-joint is laid bare. The joint is opened from the outer side by dividing the external lateral and the anterior ligaments, and disarticulation is completed as in the preceding operation.

Hæmorrhage is arrested, the distal portions of the large nerve-trunks excised, and the margins of the flap brought together and sutured. The resulting scar is situated on the posterior aspect of the stump.

Amputations through the upper-arm.—An amputation may be performed through the upper-arm at any point from the tuberosities to the condyles of the humerus. Whenever possible, a part of the humerus should be left behind, in order to provide a stump to which an artificial limb may be attached.

The forms of amputation which are practised for removal of the limb are, in the lower third, usually the circular method; in the middle and upper thirds, either the circular amputation, or, more commonly, amputation by antero-posterior cutaneo-fascial flaps, with circular division of the muscles.

FIG. 380.—Amputation through the upper-arm by the circular method.

a. Skin incision.

(a) *Amputation by the circular method.*—*Position.*—The patient is placed in the dorsal posture, with the affected limb abducted and held horizontal. One assistant grasps the hand and forearm so as to manipulate the limb during the operation, and the other stands on the right of the operator. The surgeon stands on the radial side of the right limb and the ulnar side of the left.

Operation.—The site of section of the bone being determined, a circular incision is made through the skin, superficial and deep fasciæ, $2\frac{1}{2}$ to 3 in. distal to the plane of section of the bone.

The divided tissues are dissected upwards, and turned back in the form of a cuff. The superficial muscles are divided and

allowed to retract, and then the deeper muscles cut through by making a circular sweep round the limb. Whilst these incisions are being made the limb is rotated as required, by the assistant who has charge of it.

The bone is then freed from its periosteum for a short distance, and sawn through in the usual manner.

The brachial artery is secured in the antero-internal part of the wound, and a ligature applied. The elastic ligature which controls the brachial artery (or the fingers of the assistant, if digital compression has been made use of) is relaxed, and any bleeding vessels tied. The separated periosteum is sutured over the sawn end of the humerus, the distal portions of the large nerve-trunks excised, and the divided muscles sutured to the periosteum and to one another.

FIG. 381.—Method of dissecting back cuff of skin and fasciæ.

The margins of the wound are then brought together in an antero-posterior direction, and united by the insertion of a series of sutures.

(b) Amputation by skin-flaps, with circular division of the muscles.

—The relative lengths of the anterior and posterior flaps in this operation depend upon the condition of the tissues of the limb.

As much of the limb as possible should be saved, and the skin-flaps taken from the most healthy part.

Position.—The positions of patient, surgeon, and assistant are similar to those of the preceding operation.

Operation.—An incision is made commencing on one side of the limb, extending downwards for 3 or 4 in., then transversely across to the opposite side, and upwards for an equal distance. The width of this flap ought to be half the circumference of the limb. Its distal extremity is made slightly convex.

The incision divides the skin, superficial and deep fasciæ, and then the flap is dissected up to its base by a series of light cuts. Next, a shorter posterior flap, about one-third of the length of the anterior, is fashioned in a similar manner. Both flaps are retracted by an assistant, and the muscles divided by a circular sweep of the knife down to the bone. The periosteum is cut

through, separated from the bone, and retracted for a short distance, and the bone sawn across.

Hæmorrhage is arrested in the usual manner, the divided tissues treated as described in the previous operation, and the margins of the flaps united by the insertion of sutures.

In the lower third of the upper-arm the brachial artery lies

FIG. 382.—Transverse section through middle of upper arm.

anterior to the shaft of the humerus, in the upper two-thirds it lies away from the bone on its inner side (Fig. 382).

In the formation of the flaps some surgeons adopt the "transfixion" method. This presents no advantage, however, over the one above described, and, in my opinion, ought not to be practised, for reasons already given.

Amputation or disarticulation at the shoulder-joint.—A considerable number of operations have been devised for the

removal of the upper extremity at the shoulder-joint. One of the best of these is that by the racket-shaped incision now to be described.

Position.—The patient is placed in the dorsal posture, with the affected shoulder projecting slightly beyond the edge of the operation table. The surgeon stands on the outer side of the shoulder, one assistant grasps the upper extremity at the elbow and rotates it as required, a second assistant may control hæmorrhage by applying digital pressure to the subclavian artery, whilst the third assistant helps the operator, by retracting the flaps, seizing bleeding vessels, etc.

FIG. 383.—Amputation at the shoulder-joint. Position of external incision.

- a. Coracoid process.
- b. Vertical part of incision.
- c. Circular part of incision.

Operation.—An incision is made commencing immediately below the clavicle and on the outer side of the coracoid process. It extends downwards for a short distance through the anterior fibres of the deltoid and through the pectoralis major close to its insertion, winds around the outer and posterior aspects of the arm, then across the inner aspect just below the folds of the axilla, and finally upwards until it joins the vertical portion of the first incision. In making the anterior, external, and posterior parts of the incision, the tissues are divided down to the bone, but on the inner side

the skin and fasciæ are alone divided. The vertical part of the incision should open the capsule of the shoulder-joint. The brachial artery may now be sought for at the inner side of the arm, separated from its connections, ligatured, and cut through. A flap is next dissected upwards on the inner side, comprising all the muscles, the subscapularis being detached from the lesser tuberosity of the humerus. The limb is now internally rotated, and an external flap dissected outwards in a similar manner, the supra- and infra-spinatus and teres minor muscles being detached from the greater tuberosity of the humerus. The remaining part of the capsule is divided behind,

and a cut made downwards and outwards behind the bone until the limb is freed from its connections with the trunk.

As the posterior part of the section is being made, the flaps are well retracted; and if the brachial artery has not been ligatured at an earlier stage, it is now grasped by the fingers of an assistant.

The brachial artery is now tied, together with any bleeding points becoming visible, as the pressure on the subclavian artery is relaxed, and the large nerve-trunks dissected upwards for one inch and cut across.

The entire wound is sponged dry, and the margins of the flaps united by the insertion of sutures.

In some cases it may be advisable, owing to the condition of the tissues in the neighbourhood of the shoulder-joint, to make a U-shaped flap, consisting chiefly of the deltoid muscle and the tissues superficial to it. The preceding operation, however, is generally the more suitable one, and can most often be employed with good results.

Amputation of the upper extremity.—Amputation of the upper extremity comprises removal of the arm, including the scapula and the outer two-thirds of the clavicle. The inner third of the clavicle is usually not removed unless the bone is extensively implicated in a malignant growth.

Indications.—(a) Severe injuries involving destruction of the entire upper extremity, such as gunshot wounds or machinery accidents.

(b) Malignant disease in the region of the shoulder-joint involving the scapula and clavicle, with infiltration of the lymphatic glands in the axilla.

(c) Some cases of extensive tuberculous disease extending from the shoulder-joint into the adjacent tissues.

Special instruments.—Bone forceps, periosteal elevator, small saw, lion forceps.

Position.—The position of the patient, operator, and assistants varies during the operation. In the first stage the patient is placed in the dorsal position, with the affected shoulder projecting somewhat beyond the edge of the operation table. A sandbag is placed between the scapulæ, so as to raise the diseased shoulder. The arm lies by the side. The surgeon stands on the outer side of the affected limb, with an assistant on each side of him.

In the second stage the arm is drawn away from the body, and the surgeon stands between the limb and the trunk.

In the third stage the arm is carried over the chest towards

the opposite side, and the surgeon stands on the outer side of the limb.

Operation.—The operation itself may be conveniently divided into three stages:—(a) Incision over and removal of the middle third of the clavicle, and ligature of the subclavian vessels in the third part of their course; (b) formation of the anterior flap, and division of the brachial plexus; (c) formation of the posterior flap, ligature of the posterior scapular and suprascapular arteries, and detachment of the limb.

First stage.—An incision is made commencing over the junction of the inner with the second fourth of the clavicle, and

FIG. 384.—Removal of upper extremity, including the scapula. Position of external incisions.

extending along this bone to just beyond the acromio-clavicular articulation. This divides all the soft tissues, including the periosteum, down to the bone. With a periosteal elevator the periosteum is detached from the clavicle, this detachment being aided by its division in a circular manner by the knife at the inner part of the wound. The soft parts are held aside with retractors, and the bone sawn through with a small saw at the junction of its inner and middle thirds. The outer portion of the bone is drawn outwards with lion forceps, and the soft tissues attached to its deep aspect separated. The bone is again sawn through at the junction of the middle and outer thirds, and the separated segment removed. The subclavius muscle will now be seen lying in the bottom of the wound. It is cut through just beyond its attachment to the cartilage of the first rib, and turned aside, thus exposing the subclavian artery and vein. At the

outer border of the first rib these structures are separated from their connections with the surrounding tissues, and a double ligature passed around each. These ligatures are tied so as to leave about three-quarters of an inch of the vessel between them; the vessels are then divided. The artery is ligatured and cut across before the vein, so that the limb may not remain engorged with blood.

Second stage.—The patient is drawn farther over the edge of the table, the arm pulled away from the side, and the surgeon takes up his position between the limb and the trunk.

A curved incision is then made, which commences at the middle of the clavicle, and extends downwards and outwards to the outer side of the coracoid process, and then over the anterior part of the deltoid muscle to the anterior fold of the axilla. It then crosses the upper-arm at its junction with the axilla to the posterior fold, and finally downwards and backwards to the inferior angle of the scapula. The limb is raised and rotated by an assistant as this incision is being made.

The incision first divides skin and fasciæ, a flap being dissected up and the pectoral muscles cut through. The flap thus separated is retracted to the inner side, so as to expose the brachial plexus, the cords of which are cut through just beyond the outer margin of the first rib. At the lower part of the incision the latissimus dorsi is divided a short distance from its attachment to the humerus.

Third stage.—The limb is drawn across the chest by an assistant, so as to expose the posterior aspect of the scapular region.

An incision is made commencing over the acromio-clavicular articulation at the outer extremity of the first incision, and extending downwards and backwards over the spine of the scapula to the lower extremity of the second incision. This divides skin and fasciæ only. The flap is dissected backwards, the trapezius muscle being cut through just beyond its insertion into the clavicle and scapula, until the superior angle and vertebral border of the scapula are exposed.

The limb is now allowed to hang down by the side, the anterior and posterior flaps are retracted, and then by a series of cuts the muscles which are attached to the vertebral border, the superior angle, and the superior border (rhomboides major and minor, levator angulæ scapulæ, omo-hyoid, and serratus magnus) are cut through, and the arm removed. The suprascapular artery is secured as it passes over the suprascapular notch, and the posterior scapular at the superior angle of the scapula. All

bleeding points are picked up with pressure forceps, and ligatures applied.

The margins of the flaps are brought together and fixed in position by the insertion of a series of interrupted sutures. The lower angle of the wound should be left open for drainage.

Aseptic dressings are applied and fixed in position by firm bandaging.

AMPUTATIONS IN THE LOWER EXTREMITY.

Whenever the surgeon has in contemplation removal of a portion of the lower extremity, either on account of injury or disease, he should bear in mind that the main function in man of the lower extremities is locomotion, and that all operations should leave the remains of the limb in the best condition for performing this function. Thus, when dealing with removal of the toes or parts of them, especial care must be taken not to leave any irregular or sharp prominence of bone which afterwards may easily cause abrasions of the overlying skin, and hence become the seat of commencement of inflammatory affections; and also, when removing a portion of the foot, the main flap, if possible, should always be taken from the plantar aspect, on account of the thicker covering of epithelium, and its especial fitness for coming in contact with the ground in walking. When the skin on the dorsal aspect of the foot is utilised for the main flap, and hence is made to form part of the covering of the sole, it is very unsatisfactory owing to its unsuitability for continued pressure. For those patients whom it is decided that an amputation is necessary through the limb above the ankle, the operator must have for his goal, in addition to removing the diseased or injured tissues, the creation of a stump which shall have been so designed that it permits the instrument maker to fit an artificial limb which shall be the most suitable for the position in life in which the patient is placed, and also shall be useful and painless.

Amputation of the toes.—It is advisable as far as possible, in performing an amputation, partial or complete, of any of the toes, that the flaps should be so fashioned that the scar is not placed on the plantar aspect.

An amputation of a toe may be performed either through the terminal interphalangeal or the metatarso-phalangeal joints, in most cases the latter being the better operation. Amputations through other parts of the toes are as a general rule not advisable, since the stump which is left is of no practical use, and often becomes a source of irritation.

When undertaking operations for the removal of the toes, on account of congenital deformity, injury, or disease, it is not necessary to adhere to the rule which was recommended in connection with amputations of the fingers,—to save as much of the digit as possible,—since, in the majority of patients, better functional results are obtained by removing an entire toe than by removing a portion of it. An exception to this is the case when inflammatory or tuberculous affections of the great toe are being dealt with, since here better functional results are obtained by resection of the diseased portions of the toe than by removal of the entire digit. Removal of an entire toe, with the exception just mentioned, does not seriously impair the usefulness of the foot for locomotion; hence it is usually preferable to excise the toe instead of adopting a conservative method and removing

FIG. 385.—Amputation of distal phalanx of great toe.
Skin incision.

only the diseased or deformed portion. This advice especially applies in the case of “hammer toes,” where undoubtedly better results are secured by amputation at the metatarso-phalangeal joint than by excision of the deformed articulation.

Another exception should also be noted in connection with the surgery of the toes,—as regards the treatment of dry gangrene. Here it is better to wait until the line of demarcation between the dead and living tissues has become apparent, and then to remove the dead portion of the digit at this line. The reason for this recommendation is, that if the ordinary rule of removal of the entire toe be carried out, it usually happens that gangrene of the flaps and incised surfaces follows.

Amputation of the distal phalanx—(a) Of the great toe.—The best result is obtained by making a large plantar flap.

Operation.—An incision is made commencing on the tibial

aspect of the toe just beyond the line of the articulation, passing downwards nearly to the extremity, then transversely across the pulp, and up along the fibular side to a point immediately below the line of the joint and opposite its commencement. The toe is fully extended by an assistant whilst the surgeon dissects

FIG. 386.—Appearance of toe when phalanx has been removed.

back the flap until the line of the joint is reached, the plantar ligament being divided at this stage. The surgeon now takes hold of the toe, fully flexes it, and makes an incision across its dorsal aspect. The joint is opened from above, the extensor longus hallucis tendon divided, and the lateral ligaments cut

FIG. 387.—Appearance of toe when operation is completed.

through from without inwards. The toe is now separated from its connections, and can be removed.

The digital arteries are picked up with pressure forceps and ligatured. The extensor and flexor tendons are fixed by several points of suture either to one another or to the periosteum and ligaments. The plantar flap is brought over the end of the first

phalanx, and the margins of the incision united by the insertion of sutures.

(b) **Of one of the four outer toes.**—This operation differs in no essential respect from the preceding one.

Amputation through a metatarso-phalangeal joint—(a) **Of the great toe.**—On account of the large size of the head of the metatarsal bone, it is strongly recommended that it should be removed in all cases. When this is being done, the bone should be sawn obliquely so as to remove more from the tibial aspect. Care also must be taken to make the flaps sufficiently large to afford a complete covering for the sawn surface.

Operation.—An incision is made commencing just above the head of the first metatarsal bone, extending downwards to below the line of the joint, then around the plantar aspect of the toe, and upwards upon the fibular side and across the dorsum until the vertical incision is reached. It is usually advisable to cut

FIG. 388.—Amputation of great toe through the metatarso-phalangeal joint. Skin incision.

the tissues on the plantar aspect somewhat longer than on the dorsum, and the incision may reach as low as the interphalangeal joint. The soft tissues are divided down to the bone and dissected up, the sesamoid bones being left in connection with the head of the metatarsal bone. The flaps are retracted, the tendons cut through, and the joint opened from above. The ligaments are then divided, and the toe removed.

With a metacarpal saw the head of the bone is removed, the saw cut being made in an oblique direction so as to remove more from the tibial aspect, and so avoid leaving a large prominence. The sesamoid bone also should be removed.

The digital vessels are ligatured, the tendons fixed by sutures, and the flaps brought together and fixed in apposition by sutures.

(b) **Of the little toe.**—An incision is made commencing just

above the head of the fifth metatarsal bone, and somewhat nearer the dorsal than the plantar aspect. This passes vertically downwards to a point well below the line of the joint, and then around the toe in an oval-shaped manner until it joins the vertical part of the incision. The soft tissues, including the tendons, are divided, the flaps dissected up, retracted by an assistant, and disarticulation effected by cutting through the ligaments from without inwards. The head of the metatarsal bone is now removed, either with a saw or cutting bone forceps.

The digital vessels are ligatured as before, the tendons fixed by sutures, and the flaps brought into apposition and sutured.

(c) **Of the second, third, or fourth toes.**—The toes on each side of the one to be removed are held aside with aseptic gauze by an assistant. The surgeon grasps the toe in his left hand, and makes a racket-shaped incision, commencing over the dorsal aspect of the corresponding metatarsal bone, extending downwards to a point just above the metatarso-phalangeal joint, and then around the toe at the level of the web. The flaps so marked out are dissected up, the edge of the knife being kept towards the bone, and the extensor tendons cut through.

The joint is opened from above, disarticulation completed, and the digit removed. The head of the metatarsal bone should be removed in nearly all cases.

The digital vessels are ligatured, the tendons fixed by sutures, and the margins of the flaps are brought together and fixed in apposition with sutures.

Amputation of a toe together with its metatarsal bone—

(a) **The great toe and metatarsal bone.**—A point is selected on the tibial side of the internal cuneiform bone somewhat nearer the dorsal than the plantar aspect. An incision is made commencing at this point, and extending vertically along the shaft of the metatarsal bone to a point nearly opposite the metatarso-phalangeal joint, and then around the toe in an oval-shaped manner, as in disarticulation at the metatarso-phalangeal joint. The soft tissues, including the tendons, are divided down to the bone, and the flaps dissected up. These are held aside by an assistant, and the toe forcibly pulled towards the tibial side by the surgeon, and freed from its connections with the soft tissues by a few strokes of the knife, care being taken to avoid the dorsalis pedis artery as it passes through the proximal part of the first intermetatarsal space. The joint is then opened from the dorsal aspect, the ligaments cut through, and the toe removed.

The digital vessels on the margins of the flaps are picked up

with pressure forceps and ligatured, and the tendons fixed with sutures. The margins of the flaps are brought together and fixed in apposition by the insertion of sutures.

(b) **The little toe and metatarsal bone.**—The prominent base of the fifth metatarsal bone projects backwards for some distance beyond the line of the tarso-metatarsal joint.

The apex of the tuberosity of the fifth metatarsal bone is felt for on the fibular margin of the foot, and an incision made commencing at this point, and extending distally in a vertical direction nearly to the metatarso-phalangeal joint, then round the toe in an oval-shaped manner, as in the preceding operation. The soft tissues are divided down to the bone, and the flaps dissected up and retracted by an assistant. The toe is then forcibly pulled towards the fibular side, and the connections of the metatarsal bone with the soft tissues cut through. The joint is opened from above, the ligaments divided, and the toe removed.

The digital vessels are ligatured, the divided tendons fixed, and the flaps brought together and sutured.

(c) **The second, third, or fourth toe and metatarsal bone.**—The line of the metatarso-phalangeal joint is defined, and an incision commenced on the dorsal aspect of the base of the metatarsal bone of the toe to be removed. This extends downwards in a vertical direction to a point just above the head of the metatarsal bone, and then round the plantar aspect of the toe in an oval-shaped manner. The soft tissues are divided down to the bone, and the flaps dissected up, care being taken to keep the edge of the knife always turned towards the bone.

The toe is then forcibly extended, whilst the surgeon cuts through the interosseous muscles and other soft structures with which it is connected. The joint is opened from the dorsal surface, the lateral and plantar ligaments cut through, and the toe taken away.

The blood vessels are ligatured, the tendons sutured, and the flaps brought into apposition and sutured.

Amputation through the metatarsus.—This operation is rendered necessary in some cases of severe mutilation of the distal part of the foot. No exact directions can be given for its performance, since the position of the skin incisions depends upon the amount of sound tissue available.

In all cases, however, it is advisable, if possible, to make the plantar flap larger than the dorsal. The metatarsal bones, when exposed after the flaps have been dissected back, are sawn through immediately proximal to the limits of the injury. The

various blood vessels are picked up with artery forceps and ligatured, the divided tendons fixed by sutures, and the flaps adjusted and fixed in position by the insertion of sutures.

Amputation through the tarso-metatarsal joint.—*Position.*—The patient is placed in the dorsal position, with the affected foot projecting beyond the end of the operation table. The surgeon stands in front of the foot to be operated upon, facing the sole, and his assistant opposite to him.

Operation.—Two points are defined, one the prominence of the base of the metatarsal bone on the fibular side of the foot, the other opposite the tarso-metatarsal articulation of the great toe. When this cannot readily be felt, a point is taken on the tibial margin of the foot 1 in. in front of the prominence caused by the tuberosity of the scaphoid.

FIG. 389.—Amputation of the foot through the tarso-metatarsal joint. Skin incisions.

a. Dorsal incision.
b. Plantar incision.

The foot is grasped by the left hand of the operator, and an incision made in a slightly curved direction, with the convexity towards the toes, across the dorsum, extending between the two selected points. This incision divides all the soft tissues down to the bones. The foot is now fully flexed and held by an assistant, whilst the surgeon makes the plantar incision. This commences on the fibular side of the foot at the extremity of the first incision, extends along the outer side as far as the head of the metatarsal bone, then obliquely across the sole and up the inner side of the foot until the other extremity of the dorsal incision is reached. This incision should be so made that the flap is a little longer on the tibial than on the fibular side, so as to allow a complete covering for the prominent internal cuneiform bone.

The surgeon then takes hold of the edge of the flap thus marked out with the finger and thumb of his left hand, and dissects up the flap, which should comprise all the tissues of the sole down to the bones.

The flap is dissected backwards as far as the line of the tarso-

metatarsal articulation. The foot is then forcibly depressed, and the three outer metatarsal joints opened from the dorsal aspect.

The articulation between the internal cuneiform and the base of the first metatarsal bone is opened from the inner side, and then the lateral aspects of the base of the second metatarsal are cleared by cutting towards the tarsus.

The joint between the second metatarsal and the middle cuneiform bone is opened from above, the foot further depressed, and the remaining soft tissues cut through. The foot can now be removed.

The *dorsalis pedis* artery is secured as it lies in the dorsal and internal portion of the wound, and the external and internal plantar arteries in the outer and inner parts of the sole flap, together with any other vessels from which hæmorrhage is taking place.

The plantar flap is now brought over the extremity of the stump, and its margins united to those of the dorsal flap by the insertion of a series of interrupted sutures, special care being taken to secure exact apposition on the inner side.

This operation, that is, disarticulation of all the tarso-metatarsal joints, is often known as "Lisfranc's amputation."

The operation of amputation through the tarso-metatarsal joint is now rarely performed; when an amputation is necessary in this region, the more usual practice is to saw through the tarsus on the proximal side of the injury or disease, and to effect separation in this way. This is rendered advisable on account of the lessened dangers from septic osteomyelitis after division of bones, owing to modern antiseptic methods of treatment.

Amputation through the tarso-metatarsal joints, with removal of the projecting portion of the internal cuneiform.—This operation is similar to the preceding, but instead of

FIG. 390.—Amputation of the foot at the tarso-metatarsal joint. Appearance of foot when distal portion has been removed.

performing disarticulation through the joint between the base of the metatarsal bone of the great toe and the internal cuneiform, the projecting part of the latter is sawn through. This modification is usually known as "Hey's amputation."

Amputation through the first, third, fourth, and fifth tarso-metatarsal joints, with sawing through of the shaft of the second metatarsal bone below its base.—This operation is similar to the above, with the exception that the shaft of the second metatarsal bone is sawn through in the line of the adjacent articulations. This has been called "Skey's amputation."

FIG. 391.—Amputation of the foot at the tarso-metatarsal joint. Appearance of foot when flaps have been sutured.

Amputation through the transverse or midtarsal joint ("Chopart's operation").—In this operation the portion of the foot distal to the midtarsal joint is removed, the only bones of the tarsus left behind being the astragalus and os calcis.

There is a considerable divergence of opinion among surgeons as to the comparative merits of amputation through the midtarsal joint, or "Chopart's operation," and the usefulness of the limb afterwards; in fact, some have given up the performance of the operation, on account of the retraction of the heel and the consequent painful and useless stump, and have recommended in its place either amputation at the junction of the lower and middle thirds of the leg, or at the ankle-joint. The cause of retraction of the heel appears to

have been due to non-fixation of the cut tendons on the dorsal aspect of the foot, and traction on the tendo Achillis by the somewhat unopposed posterior tibial muscles. If, after the foot has been removed through the mid-tarsal joint, the flexor and extensor tendons are joined and fixed together by careful suturing over the articular ends of the bones, and also to the cut ligaments and periosteum, this retraction in the majority of patients does not occur. The stump of the limb should be fixed and held in proper position during the process of healing,

by the application of a well-moulded poroplastic splint. When retraction of the heel has been allowed to occur, it has been treated by tenotomy of the tendo Achillis, but, as far as my observation has gone, with unsatisfactory results. When healing has taken place, the resulting stump will be found to be a very satisfactory one, since the movements at the ankle-joint are retained.

Position.—The positions of patient, surgeon, and assistant are similar to those for amputation through the tarso-metatarsal joint.

Operation.—Two points are defined,—one on the tibial aspect of the foot immediately behind the tuberosity of the scaphoid, the other on the fibular side, midway between the apex of the

FIG. 392.—Amputation of the foot through the mid-tarsal joint.
Skin incision.

a. Dorsal part.
b. Plantar part.

external malleolus and the prominence of the base of the fifth metatarsal bone.

An incision is made which extends between these two points, and crosses the dorsum in a somewhat curved direction, the convexity being towards the toes. This incision crosses the bases of the metatarsal bones, just in front of the tarso-metatarsal joints.

The foot is flexed and held in this position by the assistant, whilst the operator makes the plantar incision. This commences (in the case of the right foot) at the fibular extremity of the dorsal incision, and extends along the outer side of the foot as far as the middle of the metatarsal bone of the little toe, then crosses the sole opposite the middle of the other

metatarsal bones to the inner side, and then along the tibial margin of the foot to the inner extremity of the dorsal incision.

The plantar flap is dissected up, and made to include all the soft tissues down to the bones, until the transverse tarsal joint is reached. The operator now grasps the distal part of the foot, extends it, and divides the ligaments on the dorsal aspect of the transverse tarsal joint. Care must be taken in this part of the operation not to leave the scaphoid bone behind. This can be avoided by noting the convexity of the head of the astragalus, and the position of the tuberosity of the scaphoid.

The foot is further depressed, the interosseous and plantar ligaments divided, and any other connections severed. It can then be removed.

The dorsalis pedis artery is secured in the dorsal flap, and in the plantar the external and internal plantar arteries. Some branches of the metatarsal artery may also be found in the dorsal flap, and digital arteries in the plantar. These are picked up with artery forceps and ligatured.

All hæmorrhage having been arrested, the ends of the divided flexor and extensor tendons are approximated over the articular surfaces of the astragalus and os calcis, and fixed together by sutures; and, in addition, these tendons are fixed to the cut

ligaments and the periosteum; and, finally, the plantar flap is brought over the extremity of the stump, and its margins approximated to those of the dorsal, and fixed in position by the insertion of a series of interrupted sutures (Fig. 394).

A moulded poroplastic or gutta-percha splint is then applied, and firmly fixed by bandages. This is kept on until the wounds have entirely healed, and serves to prevent retraction at the heel.

This amputation through the transverse or mid-tarsal joint is often known as "Chopart's amputation."

FIG. 393.—Amputation of the foot through the mid-tarsal joint. Appearance of foot when distal portion has been removed.

Subastragaloid amputation of the foot.—Several varieties of this operation have been described. The following appears to give rise to the best results and to be moderately easy in its performance. It is in reality a modification of the oval or elliptical method.

Position.—The patient is placed in the dorsal posture, with the affected foot projecting for a short distance beyond the lower end of the operation table. The surgeon stands at the right side of the foot and his assistant opposite to him.

Operation.—The leg is slightly flexed at the knee, and the foot turned on its tibial side by the assistant. A point is then taken over the upper margin of the external tuberosity of the os calcis at the insertion of the tendo Achillis, and from this an incision is commenced which extends forwards to a point a short distance posterior to the prominence of the base of the fifth metatarsal bone. This incision is parallel to the external margin of the foot, and a little more than an inch below the apex of the external malleolus.

It is now carried across the dorsum of the foot in a curved direction, the convexity looking towards the distal and external part of the foot, until the inner side is reached, at a point opposite the middle of the tibial aspect of the articulation between the internal cuneiform bone and the base of the first metatarsal.

The foot is flexed, and the incision carried across the sole until it joins the first cut opposite the apex of the external malleolus.

The skin and fasciæ are cut through first, and the skin allowed to retract for a short distance. Then, by a second sweep of the knife, all the soft tissues down to the bones are divided.

The dorsal flap is dissected up for a sufficient distance, the tendo Achillis divided at the posterior part of the incision just above its insertion into the os calcis, and the posterior part of the astragalo-calcanean joint opened from its external aspect by dividing the ligaments with the knife.

FIG. 394.—Amputation of the foot through the mid-tarsal joint. Appearance of foot when flaps have been approximated and sutured.

The blade of the knife is carried forwards between the inferior aspect of the astragalus and the superior surface of the os calcis, so as to divide the ligaments which fix the two bones together. The most important of these is the strong interosseous ligament. Any tendons on the outer side which have not been divided at the second sweep of the knife are cut through along with the ligaments.

The foot is firmly twisted inwards, and by a series of short cuts with the knife the internal and inferior aspects of the os calcis are freed from their connections with the soft tissues. In this dissection the edge of the knife must be kept continually towards the bone, so as to avoid injury to the blood vessels,

FIG. 395.—Subastragaloid amputation of the foot.
Skin incision.

especially those which lie in the concavity on the internal aspect.

The foot is still more twisted, and the remaining soft structures cut through. The foot can then be removed.

In the dorsal flap, branches of the tarsal and metatarsal arteries, and of the anterior and posterior peroneal arteries, and internally the dorsalis pedis artery, will be found to be cut across and require ligature. In the plantar flap the cut ends of the internal and external plantar arteries require ligature.

The hæmorrhage having been arrested, the cut tendons are fixed by sutures, the margins of the dorsal and plantar flaps are brought into exact apposition, and fixed by the insertion of a series of interrupted sutures.

This operation does not yield a very satisfactory stump, and, in my opinion, it is often better to perform an amputation through the lower part of the leg.

Amputation of the foot through the ankle-joint by the

formation of a heel-flap and removal of the lower extremities of the tibia and fibula ("Syme's operation").

Position.—The patient is placed in the dorsal position, with the foot which is to be removed projecting beyond the end of the operation table. The surgeon stands opposite to the sole, a little to the tibial side of the left foot and the fibular side of the right. An assistant stands directly opposite to him.

Operation.—Two points are selected, one at the apex of the external malleolus, and the other a finger's-breadth below the tip of the internal malleolus. With a short amputation knife an incision is made across the sole, which joins these two points and divides all the soft tissues down to the os calcis. This incision crosses the plantar aspect not quite transversely, but sloping a little towards the heel.

The distal part of the foot is grasped by the left hand of the surgeon and depressed, and then a cut is made across the dorsal aspect of the ankle so as to join the extremities of the first incision. This incision divides all the soft tissues (skin, fasciæ, tendons, and vessels) down to the anterior surface of the joint. The anterior ligament is then divided and the joint cavity opened. The foot is further depressed, and the internal and external lateral ligaments severed with the knife. This can be aided by twisting the foot from side to side. The posterior ligament

FIG. 396. — Amputation of the foot. Short amputation knife.

FIG. 397. — Amputation of the foot at the ankle-joint. Incision in "Syme's operation."

of the joint is now cut through, and the superior non-articular surface of the os calcis exposed, together with the tendo Achillis where it is inserted into this bone.

The foot is still more depressed, the tendo Achillis divided,

FIG. 398.—Amputation of the foot at the ankle-joint. Foot removed by Syme's method.

and then all the soft tissues on the inferior and lateral aspects of the os calcis separated from their connections with the bone by a series of short sweeps with the knife. Care must be taken during the separation of this heel-flap to keep the edge of the knife against the bone, otherwise the flap will be "button-holed," or the posterior tibial artery will be wounded immediately below the internal malleolus,—an accident which is to be avoided, since it diminishes considerably the blood supply of the sole flap.

FIG. 399.—Amputation of foot at the ankle-joint. Appearance of limb when the foot has been removed by "Syme's operation."

The foot is now removed, and the bases of the flaps, where they are close to the bone, are dissected upwards for about half an inch, so as to lay bare the lower ends of the tibia and fibula for a short distance.

A saw is now taken and a thin plate of bone removed in a transverse direction. This piece of bone comprises the two malleoli, the inferior articular surface of the tibia, and a small portion of the cancellous extremities of both bones.

The bones are examined, and any carious or necrotic portions removed by scraping with a sharp spoon.

The anterior tibial artery is secured in the middle of the dorsal flap, and the internal and external plantar arteries at

the inner margin of the heel-flap, together with any branches of the peroneal artery which may be causing hæmorrhage.

All hæmorrhage having been arrested, any loose projecting pieces of tendons are cut away, and then the heel-flap is brought over the extremity of the stump, and fixed in position by the insertion of a number of interrupted silk sutures.

The operation described above is a modification of "Syme's operation." The operation as described and practised by Syme himself, was performed by dissecting up the heel-flap from below, and opening the ankle-joint in the later stages of the operation.

The modification as given above will be found to be easier of

FIG. 400.—Amputation of the foot. Position and shape of internal flap ("Roux's amputation").

performance than the "original Syme," and to yield similar results.

When the condition of the tissues in the region of the ankle does not allow of the formation of a heel-flap such as that described above, and there is plenty of sound tissue on the inner side, the amputation may be performed by making a large internal flap, as is shown in Fig. 400 ("Roux's amputation").

Neither of the two preceding operations—Syme and Roux—give very good results as regards the functions of the stump. It is very difficult to fit a satisfactory artificial foot, and in fact when this has been done it usually proves a painful stump, which does not well serve the purpose for which it was intended. For these reasons, I think the surgeon can in most instances obtain a far better functional result, and a useful and painless stump, by performing an amputation through the lower part of the middle third of the leg.

Amputation at the ankle-joint, in which a portion of the os calcis is left behind and fixed to the lower end of the tibia.—There are several modifications of this operation, which depend upon the manner in which the os calcis and the tibia are sawn.

FIG. 401.—Amputation of the foot. Lines of saw cuts in “Pirogoff’s amputation.”

The early stages of the operation are similar to those described in connection with “Syme’s amputation,” with the exception that the sole flap is made a little longer, the incision in these cases usually crossing the sole at right angles to the axis of the foot.

Fig. 401 shows the method of sawing the bones in *Pirogoff’s* operation,”

Fig. 402 in “*Sédillot* and *Gunther’s* method,” and Fig. 403 the procedure recommended by *Le Fort*.

When the bones have been sawn according to one or other of

FIG. 402.—Amputation of the foot. Lines of saw cuts in “*Sédillot’s* operation.”

FIG. 403.—Amputation of the foot. Lines of saw cuts in “*Le Fort’s* operation.”

the methods illustrated in Figs. 401, 402, 403, and the hæmorrhage from the divided blood vessels arrested, the two sawn bony surfaces are brought into exact approximation, and then

fixed by sutures either of silver wire or strong chromicised cat-gut. It is advisable also to fix the divided tendons to one another, or to the periosteum and ligaments. Next, the cutaneo-fascial flaps are coapted, and their margins carefully sutured.

The functional results which are obtainable from these operations are good, owing to the firm fixation of the bones and the thickness of the epidermal covering of the heel-flap. The operation, however, is not often available, owing to the frequency of involvement by disease of the os calcis in patients in whom amputation at the ankle-joint is considered necessary. The operation finds its most usual application after severe injuries to the greater part of the foot.

Amputations through the leg.—The occupation and wishes of the patient should always be taken into serious consideration before deciding upon the form of amputation which ought to be performed upon the leg. When it is desirable that the stump should be fitted up afterwards with a “peg-leg,” a short limb is absolutely essential, and it is recommended that the section of the bone be carried out at or immediately below the level of the tubercle of the tibia. Before the time when instrument-makers were able to make comparatively useful artificial limbs, an amputation was generally carried out through this point, owing to the ease with which a “peg-leg” could be fitted. On this account an amputation through the upper third of the leg, immediately below the tibial tubercle, was called an operation at “the seat of election.” An artificial limb, which shall be useful for locomotion, and not liable to give rise to difficulties, can be fitted to the leg when an amputation has been carried out through the middle third or the lower part of the upper third. To ensure comfort and convenience, the stump below the level of the knee-joint ought not to be less than $3\frac{1}{2}$ or 4 in. long. The most favourable seat of amputation in the leg, in patients in whom it is intended that a well-designed artificial limb shall be fitted, is the junction of the middle with the lower thirds or the lower part of the middle third. It must be remembered, however, that a sound stump, resulting from an amputation of the leg, anywhere between the junction of the lower and middle thirds and the level of the tubercle of the tibia, can be fitted with a satisfactory, useful, and painless artificial limb. When amputations are performed through the lower third of the leg, very unsatisfactory stumps result, and satisfactory artificial limbs cannot be fitted. Removal of the leg, therefore, through the lower third is not recommended, but for purposes of students attending “courses of practical operative

surgery on the dead body," some of the operations which in former times were considered desirable, are given.

Amputations through the leg may be performed by—

- (a) Antero-posterior flaps of unequal length.
- (b) Lateral flaps.
- (c) The elliptical method.
- (d) The circular method.
- (e) A long external lateral flap.
- (f) An anterior rectangular flap.

In the middle third, either the operations by antero-posterior

FIG. 404.—Amputation through the leg by a long anterior and a short posterior flap.

- (a) Anterior incision.
- (b) Posterior incision.

flaps of unequal length, and by the elliptical method, or a long external lateral muscular flap, may be made use of.

In the upper third, lateral cutaneo-fascial flaps, with circular division of muscles, or a long external muscular flap, are the most suitable operations.

(a) *By antero-posterior flaps of unequal length.*

—*Position.*—The patient is placed in the dorsal posture, with the affected limb projecting beyond the end of the table. The surgeon stands on the outer side of the right limb and on the inner side of the left.

One assistant grasps the foot, and manipulates it as required, whilst a second stands opposite to the operator.

Operation.—The longer flap may be situated on either the anterior or posterior aspects of the limb, usually the former, but this depends entirely on the condition of the tissues of the leg at the time of operation. The longer flap should be so fashioned that in width it measures half the circumference of the limb, and in length the diameter of the limb, at the level of the plane of section of the bone. The shorter flap should be about one-half the length of the longer one.

The incisions are made, and the flaps dissected up. They

should at first consist of skin and fasciæ alone, but at their base they should be made to include muscular tissue. Both flaps being dissected up, they are retracted by an assistant, and

the soft tissues divided down to the bone for the entire circumference of the limb.

The periosteum is dissected back for a short distance, and then the bones are sawn across, care being taken to complete the section of the fibula before that of the tibia. The sharp anterior border of the latter should be rounded off, as shown in Fig. 409.

When it is desired to fit an artificial limb, the fibula should be sawn three-quarters of an inch shorter than the tibia. This ensures a more conical, and therefore more useful, stump.

The anterior tibial, posterior tibial, and peroneal arteries are picked up with artery forceps and ligatured. Their relative positions are shown in Fig. 405. The large nerves are dissected upwards for 1 in., and then divided. The muscles are then fixed by sutures, both to one another and to the deep fascia, and the periosteum sewn over the ends of the bones.

The flaps are now brought over the extremity of the stump, and their margins approximated and fixed by the insertion of sutures.

(b) *By lateral flaps.*—A point is taken in the middle line of the anterior aspect of the limb at the level of the proposed plane of section of the bone, and a vertical incision is made downwards from this point for 3 in. The incision is then carried across the side of the limb in a slightly oblique direction to the middle of the calf behind, and then upwards to the level of the original incision. A similar flap is marked out on the opposite side. The two flaps are dissected up, and should consist only of skin, superficial and deep fascia.

About 1 or $1\frac{1}{2}$ in. below the level at which the bones are to be divided, the muscles are cut through in a circular direction by two or three circular sweeps of the knife. They are then dissected up for a short distance, the periosteum is divided and dissected up, and the bones sawn as before.

The vessels are picked up and ligatured, the distal portions of the large nerves dissected free and excised, the periosteum and muscles sewn together, and the margins of the flaps united by sutures.

(c) *By the elliptical method.*—The distal extremity of the ellipse may be situated either on the anterior or the posterior aspect of the limb, usually on the anterior.

The incision first divides skin and fasciæ; these are dissected up, the muscles cut through and dissected back, and the bones sawn across.

FIG. 406.—Amputation of leg by lateral flaps. Skin incisions.

(d) *By the circular method.*—The circular method presents no special features.

(e) *By a long external lateral flap.*—This operation is employed in the upper half of the leg, a thick muscular flap being obtained from the external aspect of the limb.

A point is selected in the middle of the anterior aspect of the limb at the level of the proposed plane of section of the bone, and from this an incision is commenced which extends downwards in a vertical direction for a distance equal to one-third of the circumference of the limb at the level at which the bone is to be divided. The incision is then carried round the outer aspect

FIG. 408.—Amputation of leg by large external muscular flap ("Farabœuf's operation").

The dark line shows the position of the long external incision, and the dotted line that of the short internal incision.

FIG. 407.—Amputation of leg by elliptical method. Position of skin incision.

of the limb in a gently curved direction to the middle of the calf, and then upwards to a point about 1 in. below the level at which it commenced.

The skin and fasciæ are divided for the entire length of the incision, and allowed to retract.

The limb is now turned outwards, and a second skin incision made from the posterior extremity of the first to a point $1\frac{1}{2}$ in. below the upper extremity of the anterior portion of the same incision. This second incision runs almost horizontally; it should divide skin and fasciæ, which structures are allowed to retract.

The limb is then turned on to its tibial aspect by an assistant, and the surgeon

dissects up the large external flap which has been marked out, taking up all the soft tissues down to the bone. Care must be taken not to dissect up the flap too high, otherwise

the anterior tibial artery which comes through the upper part of the interosseous membrane may be unintentionally severed. The anterior tibial artery should be divided at the lower extremity of the external muscular flap.

The muscles of the short internal flap are then divided, and the flap dissected up in a manner similar to the preceding.

The periosteum and the interosseous membrane connecting the two bones are then cut through by a circular sweep of the knife, and in favourable cases the periosteum may be separated from

the bones for a short distance. All the soft tissues, including the periosteum, are now retracted, and the bones sawn through. In sawing across the tibia, it is advisable to remove first of all a small segment of the sharp anterior border before making the transverse section. The method of doing this is shown in Fig. 409.

The vessels are ligatured, the exposed portions of the large nerves excised, the periosteum brought over the ends of the bones and fixed by the insertion of one or two points of suture, and then the flaps are adjusted and sewn up.

This method of amputating gives a stump the lower extremity of which is well covered by muscles.

(f) *By an anterior rectangular flap.*—This is generally known as “Teale’s amputation.” It is practically never advisable, in my opinion, to employ this form of operation, since it involves a considerable and unnecessary sacrifice of the healthy tissues of the limb.

The method of marking out and dissecting up the flaps is shown in Fig. 410.

The anterior flap measures in length and in breadth one-half the circumference of the limb at the level of the plane of section of the bones, whilst the posterior flap is one-quarter the length of the anterior.

Disarticulation at the knee-joint (“Stephen Smith’s operation”).—The operation of removal of the distal part of the lower extremity, by disarticulation at the knee-joint, has during recent years been less and less practised by surgeons. It has been found by clinical experience that the resulting stump tends to

FIG. 409.—Amputation of leg. Method of rounding off anterior border of tibia.

have an enlarged or bulbous extremity, and not the conical one which it ought to be the aim of the operating surgeon to produce, if he wishes to enable the instrument-maker to fit a comfortable artificial limb. The bulbous or enlarged lower end is dependent upon the width of the femoral condyles and the wasting of the muscles immediately above the level of the joint. At the time that the operation was devised, it possessed greater advantages than it does at the present day. Then, in the pre-antiseptic period, there was less possibility of the occurrence of fatal results

FIG. 410.—Amputation of leg by large anterior rectangular flap ("Teale's operation"). Appearance of parts when flaps have been dissected up.

when the operation was performed through the knee-joint than through the lower portion of the femur, owing to the fact that the medulla of the bone was not exposed. In my opinion it is better, in those cases in which removal of the lower extremity either at or immediately above the level of the knee-joint is requisite, to perform the higher operation, since a far more satisfactory functional result follows.

Position.—The patient is placed in the dorsal position, with the legs projecting beyond the end of the table. The sound leg is fixed to the leg of the operation table with a bandage, so as to be kept out of the way. The operator stands on the outer side of the right leg, and on the inner side of the left. One assistant

grasps the foot so as to manipulate the limb as required. A second assistant stands opposite the operator.

Operation.—A point is selected on the anterior border of the tibia an inch below the tubercle. With a short amputating knife an incision is made commencing at this point, extending vertically downwards on the anterior aspect of the limb for a distance of 2 in., then in a slightly curved direction with the convexity downwards round the lateral aspect of the limb to the middle line behind, and then upwards to the popliteal space as high as a point opposite the middle of the knee-joint. A similar incision

is made on the other side, care being taken to make the internal flap a little longer than the external one.

The incisions divide the skin and fasciæ, and then two flaps are dissected upwards consisting of these tissues. The ligamentum patellæ is divided, and the tissues which lie in front of the head of the tibia separated until the inferior margins of the interarticular fibrocartilages can be seen. The lateral ligaments and the anterior part of the capsule of the knee-joint are divided, and then, by a series of transverse cuts, the knife is passed through the knee-joint between the interarticular cartilages and the head of the tibia. The crucial ligaments are divided close to their attachments to the tibia. The posterior part of the joint being reached, the posterior ligament is exposed, and

FIG. 411.—Amputation of leg through the knee-joint. Skin incisions. ("Stephen Smith's operation").

may be cut through, and then with one sweep of the knife all the soft tissues in the popliteal space are divided in a transverse direction backwards.

The popliteal artery and vein are picked up and ligatured, together with any smaller vessels which may have been cut through, and then the large nerves are dissected out for 1 in. and cut across.

The flaps are adjusted over the extremity of the stump, and fixed in apposition by the insertion of sutures.

When the wound has healed, the line of the scar is situated on the posterior part of the limb between the condyles of the femur,

the extremity of the stump being well covered by soft tissues. The advantage of leaving the interarticular cartilages is that the soft parts are kept in their places, and the danger of too great retraction of the flaps is avoided.

Amputations through the knee-joint have also been performed by making a long anterior and a short posterior flap, the main features of such operations being similar to those described in connection with amputations through the leg.

Amputations through the lower fourth of the thigh.—As has already been stated, it is advisable in all cases to recommend an operation through the lower portion of the thigh in preference to one through the knee-joint. The one which is the best for practical purposes,—and enables a comfortable, useful, and painless artificial limb to be fitted to the stump,—is a combination of those which were devised and recommended by Stokes and Gritti.

Antero-posterior (long anterior and short posterior) cutaneo-fascial flaps give the best results.

Four forms of operation in this region are described; but, in my opinion, the one which will be found most valuable and assure the most useful stump is that in which the femur is divided transversely immediately above the condyles, the articular aspect of the patella is removed, and the two sawn surfaces of bone joined together. Of course, in those cases in which the patella is extensively diseased, it will not be possible to perform this operation, and one at a slightly higher level must be adopted.

Position.—The patient is placed in the dorsal position, with the lower extremities, as far as the middle of the thigh, projecting beyond the end of the table. The sound limb is fastened to the leg of the table, so as to be out of the way during the operation. The surgeon stands on the right side of the thigh which is to be operated upon; one assistant takes charge of the limb, and a second stands opposite the operator. An Esmarch's tourniquet is applied round the upper part of the thigh on the affected side.

FIG. 412. — Amputation immediately above the knee-joint by a long anterior flap. Skin incision.

Operation.—(a) *By a long anterior flap, with section of the femur immediately above the articular surface, and removal of the patella.*—This operation is often known as “Carden’s amputation.” Two points are selected, one on the outer and the other on the inner side of the thigh, at the level of the condyles of the femur. An incision is made which commences (in the case of the right limb) at the selected point on the inner side and passes downwards for about 4 in., then across the front of the leg to the outer side, and then upwards in a vertical direction to the selected point on the outer aspect of the limb. The width of the flap so marked out should be half the circumference of the limb at the plane of section, and the distal extremity should be broadly convex.

The skin and fasciæ are divided for the entire length of the

FIG. 413.—Lower end of femur, showing positions of section of bone—

- a. In “Carden’s amputation.”
- b. In “Gritti’s amputation.”
- c. In “Stokes’s amputation.”

incision, and the flap dissected upwards until the upper border of the patella is reached. The muscles attached to the superior margins and the lateral borders of the patella are cut through, and the knee-joint opened. The muscles are allowed to retract, and the flap dissected upwards to just above the level of the plane of section of the bone.

A long amputation knife

is now passed behind the bone from the outer to the inner extremity of the first incision. The cutting edge is turned backwards, and all the soft tissues divided by cutting directly towards the surface.

The soft parts are retracted by the assistant, the femur is cleared for a short distance above the articular surface, and the bone sawn through (Fig. 413, a). The limb can now be removed.

The thigh is flexed so as to expose the cut surfaces of the flaps, and the popliteal artery and vein secured. The tourniquet is removed, and all other bleeding vessels (branches of the anastomosis around the knee-joint) are likewise ligatured. The large nerve trunks are directed upwards for 1 in., and the exposed portions removed.

The broad anterior flap is brought over the extremity of the bone, and fixed in position by the insertion of sutures.

In many cases it will be advantageous to make a short posterior flap, in addition to the long anterior one, in order to provide an efficient covering for the stump.

(b) *By a long anterior flap, with section of the femur through the condyles and removal of the articular aspect of the patella* ("Gritti's operation").—This form of operation resembles the preceding, except that the knee-joint is opened below the patella, the ligamentum patellæ and the inferior part of the capsular ligament being cut through, and the patella dissected up in the anterior flap. The articular surface of the patella is removed with a fine saw. When the flap is brought into position, the cut surface of the patella should lie in apposition with the sawn extremity of the femur, the two bones becoming firmly united as healing takes place.

Much difficulty is often experienced in keeping the sawn surfaces in apposition, owing to the action of the muscles and the length of the femur. In order to obviate this, the following operation has been proposed, and in many instances gives rise to a better result than the preceding:—

(c) *By a long anterior flap, with section of the femur above the condyles and removal of the articular aspect of the patella* ("Stokes's operation").—This operation resembles the preceding in all essential respects, with the exception that the femur is sawn through at a higher level,—through the shaft immediately above the condyles (Fig. 413, c),—and the skin-flaps are commenced at a slightly higher level. The sawn surface of the patella can be brought into and kept in apposition with the sawn surface of the femur much more readily than in the preceding operation. In order to effect this, it is usually advisable to fix them together by one or two sutures of silver wire, inserted at the posterior margin of the sawn surfaces.

(d) Ssabanajeff has further modified this operation. He saws the lower end of the femur in a manner similar to Gritti, but leaves the patella intact. A segment of the tibia is fashioned by first sawing the bone in a vertical direction to a point a short distance below the tubercle of the tibia and the attachment of the ligamentum patellæ, and then transversely until the second saw cut meets the first. By this method a portion of the tibia and the insertion of the quadriceps extensor muscle are separated. The sawn surface of the segment of the tibia and that of the lower end of the femur are brought into exact apposition, and fixed by the introduction of sutures. The advantages which are claimed for this method are the retention of the insertion of the quadriceps extensor muscle, the readiness with which the bony

surfaces of the tibia and femur unite, and the more satisfactory stump which results. This procedure may be available in cases of injury and in early cases of tuberculous disease, but in

advanced cases the state of the bones will not allow of its performance.

In the four preceding forms of amputation, the resulting scar

will lie on the posterior surface of the limb, and the covering for the end of the stump will be formed from the skin over the patella and the extensor aspect of the knee, which is well fitted to withstand pressure.

Amputations through the middle of the thigh.—Amputations through the middle portion of the thigh may be performed by the following methods :—

(a) By antero-posterior cutaneo-fascial flaps, with circular division of the muscles ; (b) by lateral cutaneo-fascial flaps, with circular division of the muscles ; (c) by the circular method ; (d) by the elliptical method ; (e) by a long anterior muscular flap.

Of these forms of operation, those by antero-posterior or lateral cutaneo-fascial flaps, with circular division of muscles, are the best in the majority of instances. In all cases sufficient allowance must be made for retraction of muscles, the periosteum dissected upwards for 1 in. and afterwards sewn over the divided end of the bone, the large nerve trunks dissected out for a sufficient distance, and in sewing up the wound buried muscular sutures should be inserted.

Position.—The positions of the patient, surgeon, and assistants are similar to those in amputation through the lower fourth of the femur, with the exception that the affected limb should project further beyond the end of the table.

The elastic tourniquet is placed on the thigh well above the level of the plane of section of the bone.

Operation.—(a) *By antero-posterior cutaneo-fascial flaps, with circular division of the muscles.*—A U-shaped incision is made commencing on the side away from the operator, at the level at which it is proposed to divide the bone, and extending first vertically downwards, then transversely across the front of the limb, and finally vertically upwards to a point opposite that at which it commenced.

This incision marks out a flap with a broadly rounded ex-

FIG. 415.—Amputation through the thigh. By unequal antero-posterior cutaneo-fascial flaps, with circular division of muscles.

- a. Anterior flap.
- b. Posterior flap.
- c. Section of bone.

tremity, in width equal to half the circumference, and in length to the diameter, of the limb, at the level of the plane of section of the bone. The incision divides the skin, superficial and deep fasciæ, and these structures are dissected up to form the flap. A similar flap, half the length of the anterior one, is then marked out, and dissected up on the posterior aspect of the limb. Both flaps are retracted by an assistant, and with a circular sweep of the knife the muscles are divided down to the bone. The periosteum is cut through and retracted for a short distance, and the femur sawn across.

FIG. 416.—By equal antero-posterior cutaneo-fascial flaps, with circular division of muscles.

- a. Anterior flap.
- b. Posterior flap.
- c. Level of section of femur.

The superficial and deep femoral vessels having been secured, the tourniquet is relaxed, and any bleeding points picked up and ligatured. The periosteum is sewn over the end of the femur, the portions of the large nerve trunks—sciatic and anterior crural—resected, and the cut ends of the muscles sutured.

The margins of the cutaneo-fascial flaps are then approximated, and united by sutures in the usual manner.

The relative lengths of the flaps may vary according to the condition of the soft tissues. The flaps should be long enough to meet without tension, and to provide a scar which shall not lie immediately over the end of the bone.

(b) *By lateral cutaneo-fascial flaps, with circular division of the muscles.*

—This operation is similar in many respects to the preceding, but the

skin incisions commence and terminate on the anterior and posterior aspects of the limb respectively, two equal lateral flaps being formed (Fig. 417).

(c) *By the circular method.*—A circular incision is made through the skin, superficial and deep fasciæ, 3 to 4 in. below the level at which it is proposed to saw the bone.

The divided tissues are dissected back in the form of a “cuff,” and then with a circular sweep of the knife the superficial layers of muscles are cut through; these are allowed to retract, and then the deeper muscles are divided in a similar manner down

to the bone. The latter is freed from its periosteum for a short distance, and then sawn through in the usual manner. All hæmorrhage having been arrested, the margins of the wound are brought together and fixed by the insertion of sutures.

(d) *By the elliptical method.*—Amputation by the elliptical method through the middle of the thigh is similar to amputation by the same method in other parts.

The distal extremity of the ellipse may be either anterior or posterior, preferably the former.

(e) *By a long anterior muscular flap.*—When this operation is performed, a long U-shaped flap is dissected up from the anterior aspect of the limb. At first it consists of skin and fasciæ, and then it includes the muscles.

It is, however, very rarely necessary to employ this form of amputation.

Amputations through the hip-joint.—Several varieties of operation are practised for the removal of the lower extremity at the hip-joint. These are the “racket” method (of Furneaux Jordan), antero-posterior flaps, lateral flaps, and the formation of flaps by transfixion.

The best method for amputation in cases of extensive disease of the hip-joint is that of Furneaux Jordan. It involves less loss of blood than any of the other methods, and provides a wound the cut surfaces of which can be fairly readily kept in apposition.

Position.—The patient is placed in the dorsal position, with the lower extremities and the buttock of the affected side projecting beyond the edge of the table. The sound limb is drawn aside and fixed to the leg of the table by a bandage. The surgeon stands on the right side of the affected limb. One assistant grasps the lower portion of the diseased limb and rotates it as required; the second assistant stands to the right of the operator; a third assistant attends to the control of the blood vessels.

The circulation is best arrested by passing a strong elastic tourniquet around the junction of the thigh with the pelvis.

FIG. 417.—By lateral cutaneous-fascial flaps, with circular division of muscles.

a. External flap.

b. Internal flap.

c. Level of section of femur.

This tourniquet is passed after the anæsthetic has been administered. The posterior part crosses the ischio-rectal fossa on the inner side of the ischial tuberosity. One end is brought round in front over the inguinal region, and the other round the gluteal region. The two ends meet over the highest part of the iliac crest.

A calico bandage is placed over the middle of Poupart's ligament, and underneath the rubber tube. When the ends of the tourniquet have been tightened, the calico bandage compresses the lower part of the external iliac artery, and the rubber tube the distal portions of the gluteal and sciatic vessels. A

- b. Vertical portion of incision.
- c. Position of top of great trochanter of the femur.

third assistant attends to this tourniquet throughout the operation, and takes care to keep the calico bandage in front of the external iliac artery.

Before the tourniquet is applied, the limb is elevated and the blood allowed to run out of it, in order to minimise the shock which usually follows loss of blood.

Operation.—A circular incision is made through the skin and fasciæ in the middle of the thigh, and the incised tissues dissected upwards for a distance of 2 in. With one or two circular sweeps of the long amputation knife, all the soft tissues, including the blood vessels, are divided down to the bone. The cut ends of the femoral vessels are now sought for in the antero-internal part of the wound, and ligatured.

The patient is now turned a little on the sound side, so as to more fully expose the gluteal aspect of the limb.

A vertical incision is made along the outer aspect of the thigh, commencing at a point half-way between the apex of the great trochanter and the iliac crest, and terminating in the circular incision below. This cut is made with a short amputation knife, and all the tissues down to the femur are divided.

Next, the flaps are dissected up on each side, all the soft tissues being included, and the femur cleared from its connections with the muscles. Most difficulty will be experienced in detaching the muscles from the *linea aspera*. The femur is

rotated by the assistant who has charge of the limb, as this dissection proceeds.

The capsular ligament of the hip-joint is incised above and in front (if it is not already destroyed by disease), the femur is

powerfully externally rotated, so as to make the head protrude from the acetabulum; the ligamentum teres and the posterior part of the capsular ligament are divided; and then, any other soft tissues which are still attached to the femur are cut through with a few strokes of the knife.

The limb is now separated from its connections, and can be removed. Any bleeding points which may be apparent are picked up with pressure forceps and ligatured. The region of the acetabulum is then examined, and if any diseased bone is discovered it is scraped away with a sharp spoon. The large nerve trunks are dissected upwards for $1\frac{1}{2}$ in., and cut across and removed. The elastic tourniquet is gently relaxed, and any bleeding vessels which become visible are seized with forceps and ligatured.

All hæmorrhage having been arrested, and the tourniquet removed, the cut surfaces of the flaps are brought into apposition and fixed by the insertion of sutures. The angles of the wound may be left open and a drainage tube passed into the depths of the wound, and then the stump is carefully and firmly bandaged.

The main branches of the gluteal artery are not interfered with, and only one of the lowest branches of the sciatic is cut across.

If it is wished to minimise the loss of blood, the femoral vessels should be isolated during the first stage of the operation, ligatured in two places, and cut through.

The other methods of amputation through the hip-joint are not so satisfactory in cases of extensive disease as the one above described, but are better adapted for primary amputation after injury.

They resemble in most respects similar amputations in the middle of the thigh.

CHAPTER XXVIII.

OPERATIONS UPON THE MAMMARY GLAND.

OPERATION FOR MAMMARY ABSCESS.

REMOVAL OF LOCALISED NON-MALIGNANT TUMOURS AND CYSTS.

REMOVAL OF THE BREAST—

- (a) Without removal of the lymphatic glands from the axilla.
- (b) With removal of the lymphatic glands from the axilla.

THE mammary gland is situated on the antero-lateral aspect of the chest wall, and lies between two layers of the superficial fascia. In front of it lie the skin and the anterior lamina of the superficial fascia, and behind it the deep lamina of the superficial fascia, the deep fascia, and the pectoral muscles covering the surfaces of the ribs and the intercostal spaces.

The gland is divided into a number of lobes, these lobes being separated from one another by processes of fascia. Fig. 420 is a diagrammatic representation of a horizontal section of the mammary gland.

FIG. 420.—Diagrammatic representation of the structure of the mammary gland.

- a. Lobule of gland.
- b. Connective tissue septa which separate the lobules from one another.
- c. Ducts of gland passing to the nipple.

OPERATION FOR MAMMARY ABSCESS.

An operation is indicated in all cases of inflammation of the breast in which the formation of pus has taken place. Before

undertaking an operation for the evacuation of the pus, the locality and extent of the abscess should be ascertained as far as possible by careful palpation.

Operation.—The position of the abscess having been ascertained, an incision is made over the prominent portion, commencing a short distance outside the nipple, and radiating outwards from this point toward the periphery of the gland. The length of the incision varies according to the extent of the abscess cavity. When the interior of the abscess is reached, the margins of the incision are separated with dressing forceps or the fingers, and the pus allowed to escape.

The pus having been evacuated in the above manner, the forefinger is passed into the abscess cavity and an examination made of its interior, so as to discover any adjacent collections of pus which have not been opened by the first incision.

The majority of acute abscesses of the breast are multilocular, and involve several lobes of the gland. The strong connective tissue septa which separate the lobes from one another are not disintegrated so readily by the inflammatory process as the glandular tissue. If further collections of pus are discovered, the fibrous septa separating them from the cavity of the abscess which has been opened are completely broken down with the finger, in order to allow the escape of the contents, and to provide free drainage. If it is difficult to establish thorough drainage from a single incision, owing to the size of the abscess, a second and even a third incision may be made. These should radiate from the nipple, and be placed at the lower limits of the abscess cavity.

When free communications have been established between the abscess cavity and the exterior, and all pus has been evacuated, the interior of the abscess is thoroughly swabbed out and irrigated with an antiseptic solution.

Next, drainage tubes are inserted, or the interior may be packed with antiseptic gauze, and antiseptic dressings applied and fixed in position by firm bandaging.

The arm of the affected side should be fixed in front of the chest, in order to avoid contractions of the pectoral muscles, and so help to maintain the inflamed tissues in a condition of rest.

When the abscess is situated behind the mammary gland, it will be found more convenient to lift up the organ towards the neck, and to make the incision in the sulcus between the gland and the chest wall. No visible scar will result from this procedure.

REMOVAL OF LOCALISED NON-MALIGNANT TUMOURS AND CYSTS FROM THE MAMMARY GLAND.

Adenomata, fibro-adenomata, fibromata, and simple cysts are frequently met with affecting the mammary gland, and when present require removal.

Operation.—An incision is made over the prominent part of the tumour, in a direction radiating from the nipple. The skin and fasciæ are divided, and the tumour exposed. This is dissected from its surroundings, and removed. Hæmorrhage is arrested, and the external wound closed in the usual manner. Dressings are applied, and the limb bandaged to the chest, as in the preceding operation.

When the tumour or cyst is situated in the lower part of the mammary gland, an incision may be made in the sulcus between the organ and the chest wall, the gland incised from its posterior aspect, so as to expose the deep surface of the tumour or cyst, and through this opening the abnormal structure is removed. No visible scar results from the procedure.

REMOVAL OF THE BREAST.

Removal of the breast not accompanied by removal of the lymphatic glands of the axilla.—*Indications.*—(1) Chronic interstitial inflammation of the breast, which is not amenable to ordinary palliative measures.

(2) Tuberculous disease of the breast associated with numerous sinuses.

(3) Actinomycosis of the breast.

(4) Serocystic disease of the breast, in which the whole or the greater part of the organ is involved.

(5) Very early cases of carcinoma of the breast, in which the disease commences in the internal margin.

Position.—The patient is placed in the dorsal position on the operation table, with the affected side close to the edge. The upper extremity of the diseased side is held at right angles to the trunk by an assistant. The surgeon stands on the affected side of the patient and his assistant on the opposite side.

Removal of the breast (without clearing out of the axilla).—An oval-shaped incision is made, which includes the nipple and the areola, as shown in Fig. 421. The upper part of this incision is made first, and divides the skin and superficial fascia, and exposes the anterior aspect of the gland. The skin and fascia are dissected upwards until the superior margin of the

OPERATIONS UPON THE MAMMARY GLAND.

ama is exposed; this is pulled downwards, and the dissection continued on its posterior aspect. When the upper part of the breast has been freed, the organ is retracted upwards by an assistant, and the lower half of the incision made. The skin and fascia are dissected up until the inferior margin of the gland is laid bare, then by a few strokes of the knife the posterior aspect is separated from the fascia, and the gland removed.

In cases of inflammatory or of cystic disease of the mammary

FIG. 421.—Removal of breast. Skin incision.

gland, the dissection should not extend beyond the superficial surface of the pectoral fascia. When, however, the gland is being removed for early carcinoma, situated in the internal margin, it is advisable to remove freely the pectoral fascia and the underlying part of the pectoralis major, since the lymphatic vessels run through the fascia and muscle on their way to the intercostal spaces and the interior of the chest.

When the gland has been removed, all bleeding vessels are tied, the interior of the wound sponged out, and its margins

united by the insertion of interrupted sutures. Dressings are applied, and the arm bandaged to the chest, as in the previous operation.

Removal of the breast, together with the lymphatic glands from the axilla and the peri-mammary tissues.—

Indications.—1. *Carcinoma of the breast.*—It has now been almost universally decided, by surgeons who have had extensive experience in operations upon patients suffering from carcinoma of the mammary gland, that in almost all cases of this disease (with the possible exception of those cases in which the disease commences in the sternal margin of the gland), which are amenable to operation, and there are no marked contra-indications, that the mammary gland, the overlying skin of the mammary region, including the nipple and areola, the surrounding connective tissue containing lymphatic vessels and fat, the underlying pectoral fascia and sternal portion of the pectoralis major muscle, the axillary groups of lymphatic glands which receive the lymphatic vessels from the mammary gland and mammary region, and the connective tissues and fat in the axilla, should all be removed. The operation should be so designed and carried out that all the tissues above enumerated are taken away in one mass.

Concerning the question of dividing the pectoralis minor muscle, the surgeon should never hesitate to cut through or remove a segment of this muscle, if it facilitates removal of the axillary tissues, and so ensures complete removal of all possibly cancer-infected areas. Removal of a portion of the pectoralis minor, or transverse division of it, does not seriously impair the usefulness of the limb beyond that which has been effected by the other parts of the operation. Personally, I think that a portion of the muscle ought to be removed in all extensive cases of carcinoma, and also in those early cases in which the disease commences in the upper portion of the mammary gland, since the lymphatic vessels from this portion of the breast join the lymphatic glands upon the costo-coracoid membrane, and in their course to these glands they pass through the fascia which forms a sheath to the muscle.

When the supraclavicular lymphatic glands are enlarged in carcinoma of the breast, the primary disease, together with the lymphatic glands, may be removed; but it is rarely possible to effect complete removal of the affected glands at the root of the neck. In this case, however, the secondary growths do not always increase in size very quickly, so that it often happens

that life is prolonged for a considerable time after the removal of the primary disease.

2. *Sarcoma of the breast*.—If there are signs or symptoms which justify a diagnosis of the presence of secondary growths in any of the viscera or bones of a patient suffering from sarcomatous disease of the breast, it is not advisable to perform an operation for the removal of the primary disease. When, however, there are no contra-indications of this kind, removal of the breast should be invariably carried out. In early cases

FIG. 422.—Diagrammatic representation of the course of the lymphatic vessels from the breast, and the groups of glands into which they open.

- a. Mammary gland.
- b. Lymphatic glands along long thoracic vessels.
- c. " " between the two pectoral muscles.
- d. " " in middle of axilla.
- e. " " along the axillary vein.
- f. " " upon costo-coracoid membrane.
- g. " " in anterior and superior mediastina along the internal mammary vessels.
- h. Thoracic duct or right lymphatic duct.

of the disease, it is not usually necessary to remove the axillary contents, as has been recommended in the case of carcinoma; but whenever there are signs that the disease has commenced to infiltrate the surrounding tissues, the complete operation should be performed.

3. *Tuberculous disease of the breast associated with a similar affection of the axillary lymphatic glands*.—Tuberculous disease of the breast is not very common; when, however, it occurs, it usually, at a comparatively early stage, causes a similar affection of the lymphatic glands in the axilla. The breast and axillary

lymphatic glands should be removed, but it is not generally necessary to remove the sternal portion of the pectoralis major.

Removal of the breast together with the lymphatic glands from the axilla.—The lymphatic vessels from the external portion of the breast pass outwards and join the lymphatic glands in the axilla, from the upper part they go to those on the costo-coracoid membrane, and from the internal margin to those in the superior mediastinum. Fig. 422 is a diagrammatic representation of the course of the lymphatic vessels from the mammary gland to the different groups of lymphatic glands to which they go. The majority of the lymphatic vessels from the breast pass into the axilla, a few from its upper margin to the glands on the costo-coracoid membrane, and those from the internal portion to the glands within the chest.

Position.—The patient is placed in the dorsal position with the affected side of the thorax projecting slightly over the margin of the operation table. The shoulders are slightly raised by placing a pillow or other support underneath them. The upper extremity of the affected side is abducted and held at right angles to the trunk by an assistant who is detailed for this purpose. This assistant manipulates the limb, if requisite, during the course of the operation. The surgeon stands on the affected side of the patient between the abducted upper extremity and the trunk, and his chief assistant opposite to him.

Operation. — *Skin incisions.* — The exact lines of the skin incisions vary according to the site of the carcinoma in the mammary gland, and the amount of the involvement of the skin, if any. Usually they are elliptical or pyriform in shape, the broad part enclosing the mammary prominence, and the narrow being extended along the anterior fold of the axilla to a point where the upper extremity joins the trunk. Figs. 423 and 424 represent the more useful forms of incision which can be adopted in removal of the breast and axillary contents. The essential points which every one must observe in making the skin incisions is to be certain that they are wide of any involved area, and that they do not extend in depth beyond the skin and subcutaneous fascial layer. The mammary gland lies between two layers of superficial fascia; hence, if great care be not taken in dissecting back the skin flaps, superficial and outlying portions of the mammary gland will be left behind, and become the starting-points of a local recurrence of the disease. When operating upon the right breast, the skin incision commences at the anterior fold of the axilla, where the upper extremity joins the trunk, and then proceeds in an elliptical manner inwards

and downwards over the anterior fold of the axilla, and the pectoral and mammary regions, until a point is reached near the lateral margin of the sternum, and below and internal to the

FIG. 423.—Removal of breast and contents of axilla.
Line of pyriform incision.

lower portion of the inner and inferior quadrant of the mammary gland. The second portion of the incision is also elliptical in shape, encircles the mammary eminence, and extends from the

FIG. 424.—Removal of breast and contents of axilla.
Line of skin incisions.—HALSTED.

termination of the first incision, below, around, and external to the breast until it joins the first about the middle of the anterior fold of the axilla. The exact directions of these incisions vary a little according to the locality of the cancerous mass, but in

all cases they encircle the entire mammary eminence, and some of the adjacent skin (Figs. 423, 424). The skin along the entire margins of the wound is dissected up from the underlying tissues, until the confines and boundaries of the mammary gland and any of its prolongations have been passed. The deeper fat and fasciæ are now cut through in the upper part, and the sternal portion of the pectoralis major and its sheath of deep fascia exposed (Fig. 425). The scalpel is next carried through the pectoralis major muscle, together with the fascia lying above and below it, and the muscle separated from its attachments and connections with the thoracic wall. At this

FIG. 425.—Removal of breast and contents of axilla. Appearance of wound when upper portion of incision has been made.—HALSTED.

stage the perforating branches of the internal mammary artery will be cut through and require ligature. By this dissection the entire mass which is to be removed can be thrown outwards, and then the pectoralis major muscle is cut through near to its attachment to the humerus. The costo-coracoid membrane, the pectoralis minor, and the upper portion of the axilla are now fully exposed. The connective tissue and lymphatic vessels and glands which lie above the pectoralis minor, and in relation with the costo-coracoid membrane, should be separated by careful dissection, and removed, together with the thin fascial envelope of the pectoralis minor. By these proceedings the pectoralis minor and its external border are laid bare. This muscle is now divided

transversely, and, if considered requisite, a segment taken away. The margins of the upper portion of the incision are now pulled upwards and inwards by means of a broad retractor, and then the surgeon dissects away the connective tissue, fat, lymphatic vessels, and glands from the inner side of and surrounding the axillary vein, and the lower portion of the subclavian vein. Considerable care is required during this part of the operation to ensure complete removal of all possibly infected tissues, and to avoid injury to the large vessels. Special attention should be directed to the removal of the processes of connective tissue which pass in front of and behind the axillary vessels. When the vessels have been cleaned thus, the mass is retracted downwards and outwards by the assistant exerting traction upon it. The surgeon dissects the mass away from the lateral wall of the thorax and the inner wall of the axillary space, care being taken to detach the fascia from the external aspect of the serratus magnus muscle. As this dissection is being performed, the branches of the large vessels are cut and ligatured as they become exposed.

When this has been done, and the junction of the posterior and lateral walls of the axilla reached, the assistant is directed to retract outwards the skin which forms the outer and posterior part of the original incision, and at the same time the surgeon so grasps the tumour mass and exerts traction as to stretch the vessels and nerves which pass to the muscles which form the posterior axillary wall. The axillary contents, by dissection from above and internally downwards and outwards, are carefully separated from the posterior axillary wall, the vessels being seized with pressure forceps as exposed before division, and the subscapular nerves, if possible, being saved. Great care should be taken to remove the connective tissue and enclosed lymphatic glands which lie in the angle between the serratus magnus and the lower part of the subscapularis. When the posterior and lower portion of the axilla has been reached, one or two cuts are made in an outward direction, and then the entire mass can be removed. Fig. 426 shows the appearance of the mass when removed.

All bleeding points are now secured with ligatures, and the pectoralis minor, if simply divided, united by sutures. If there is any difficulty in thoroughly exposing the tissues in the region of the costo-coracoid membrane, a cut may be made at right angles to the upper portion of the incision, so as to give a better exposure; and when the supra-clavicular lymphatic glands are enlarged, this cut may be extended into the posterior

triangle of the neck, and through it any enlarged glands taken away. It is not necessary to divide the clavicle in order to obtain complete exposure of the supra-clavicular lymphatic glands.

Closure of the external wound.—This is not usually possible, but much aid can be obtained very often in this respect by making incisions backwards and forwards, and dissecting up the skin as in a plastic operation. Often the wound can be com-

FIG. 426.—Removal of breast and contents of axilla. Appearance of mass, consisting of mammary gland, skin, axillary lymphatic vessels, and glands and fat, and portions of pectoral muscles.—HALSTED.

pletely closed in by this proceeding. On three occasions, in the case of women with very pendulous breasts, in whom it was necessary to remove a considerable part of skin, I was enabled to absolutely close the wound, by dissecting up the breast of the opposite side, freeing it at its lower and external margins, and transplanting it so as to cover the entire wound.

When it is not possible or advisable to close the external wound by skin, it is recommended that at a later date

the unclosed area be grafted with skin grafts by Thiersch's method.

After-treatment.—When the dressings have been applied, the arm of the affected side is secured to the side of the chest by firm bandaging, and kept in this position for four or five days. It is then released, and the patient encouraged to move it slightly. This precaution avoids unnecessary delay in recovery of the use of the arm, as almost invariably follows when the limb is kept fixed to the side for a longer period.

The results which have followed this form of operation are much better than were obtained by the older methods of removing merely the breast and any lymphatic glands which happened to be enlarged. The latest statistics appear to conclusively show that in favourable cases 40 to 50 per cent. of recoveries may be expected.

PLASTIC SURGERY.

By the term "plastic surgery" is understood those operative measures which have for their object the repair of malformations or deficiencies which are due to congenital or acquired causes.

The congenital malformations which are most common, and which can be repaired by surgical aid, are the different varieties of hare lip and cleft palate, and malformations of the genital organs, such as epispadias, hypospadias, and extroversion of the bladder. Webbed fingers occasionally occur, and can be remedied by surgical treatment.

Acquired malformations may be dependent either upon disease or upon injury. The former class includes loss of part or the whole of the nose by ulceration, and the different forms of contraction which cause deformities and are due to the scars of healed ulcers. The deformities or deficiencies which are due to injury may be the result of severe contractions after burns, to the accidental removal of some part, such as the nose, by a sharp instrument, or to the removal of some organ by the surgeon in the treatment of a disease, especially a malignant growth, such as a rodent ulcer.

Skin grafting is so intimately associated with many forms of plastic operations and the repair of defects, that it has been considered advisable to include it in this chapter.

HARE LIP.

A hare lip is a congenital affection which is due to the non-closure or incomplete closure of the original cleft between the central and lateral portions of the upper lip. When it occurs on one side only it is called a *single* hare lip, and when on both sides a *double* hare lip. A *median* hare lip may occur, but it is exceedingly uncommon. When present it is usually associated with non-development of the intermaxillary bone, but cases have been seen in which this bone has been fully formed. In this latter case possibly a lateral cleft has been drawn towards the middle line.

Period of life at which the operation is best performed.—The period of life at which the repair of a hare lip ought to be carried out has varied in the practice of different surgeons. Operation at some date between the termination of the fourth week and that of the fourth month appears to have been followed by the best results, the most favourable time being between the sixth and eighth week.

If the operation is performed after the end of the sixth month, the complications of dentition are liable to interfere with the success of the operation, and before the fourth week an infant is not always strong enough to stand such an operation.

(a) **Single hare lip.**—*Special instruments.*—Long-handled fine scalpel or tenotome, fine-toothed long-handled forceps, suture material (fine salmon-gut or horse-hair).

Position.—The patient is placed in the dorsal posture on the operation table, with a sterilised towel wrapped around the chest and arms. The operator stands at the head of the patient, the assistant on the affected side, and the anaesthetist on the opposite side.

Chloroform is the anaesthetic which should be used, and care must be taken that no drops of it fall on the face of the infant, especially in the region of the wound.

Operation.—The operation for the cure of hare lip may be divided into four stages, namely—(a) Incision of the mucous membrane at the reflection between the cheek and the alveolar process, and separation of the two parts of the lip from the external surfaces of the maxillary bone; (b) paring of the margins of the cleft in the lip; (c) fixation of the prepared

margins and surfaces in apposition, by the insertion of sutures; (d) application of a dressing which shall maintain the parts in position.

(a) *Incision of mucous membrane.*—The margins of the cleft portion of the lip are held apart, and the mucous membrane on the internal surface cut through along its line of reflection from the gums. Next, the lip is dissected upwards for a short distance, so as to allow the easy approximation of the margins of

FIG. 427.—Single hare lip. Positions of incisions along the margins of the cleft.—W. ROSE.

FIG. 428.—Single hare lip. Appearance of the upper lip after the cleft has been closed.—W. ROSE.

FIG. 429.—Single hare lip. "Nélaton's operation." Position of the incision.

FIG. 430.—"Nélaton's operation." Appearance of parts after the incision has been made, the apex of the cleft drawn downwards, and the sutures inserted.

the cleft without the production of tension. In severe cases it may be necessary to effect this separation almost to the infra-orbital foramen on the affected side. The attachment of the ala of the nose to the superior maxilla is also cut through during the separation of the tissues of the cheek. This avoids flattening and malformation of the nostril of the cleft side.

Whilst this separation of the tissues of the cheek is being effected, the edge of the scalpel should be kept turned towards the surface of the maxilla, and away from the cheek.

Any hæmorrhage which occurs can usually be controlled by sponge pressure.

(b) *Paring margins of cleft.*—The methods of paring the edges of the cleft in the lip vary according to the characters of each individual case. The main points to be borne in mind are that the margins of the incision shall correspond, that the line of union of the cleft shall be a little longer than is apparently

FIG. 431. — "Nèlaton's operation." Appearance of the lip when the sutures have been tied and the operation completed.

It is only in slight and extremely favourable cases that a good result can be obtained by this procedure.

FIG. 432. — Single hare lip. Operation of Malgaigne. Position of incisions at the margins of the cleft.

FIG. 433. — Single hare lip. Operation of Malgaigne. Appearance of cleft when the margins have been pared and the sutures inserted.

requisite, so as to allow for contraction of the scar tissue along the line of union, and to see that the red line of the lip is quite regular and even.

A thin-bladed scalpel is taken, its point entered at the apex of the cleft or at the nostril (when the malformation is complete), with the cutting edge towards the mouth, and then a cut is made in a straight or somewhat curved direction as far as

the junction of the skin with the mucous membrane, then the blade is turned towards the cleft and a further cut made at an angle of 50° to 70° , according to the width of the cleft. The manner of making this incision is shown in Fig. 427. This is the operation which is recommended by Professor Rose. Other methods of making the incisions in the margins of the cleft are shown in Figs. 429, 432, and 435.

The other side of the cleft is then treated in a similar manner, the hæmorrhage being controlled by the fingers of the assistant, or by putting on a suitable lip compressor. Usually it will be found more convenient to adopt digital pressure.

(c) *Insertion of sutures*.—The margins of the cleft having been prepared as above, are brought together and fixed in this position by the insertion of a series of simple interrupted sutures.

Fine straight needles are taken, and threaded with fine salmon-gut. The first needle is passed a little above the junction of the skin with the red portion of the lip, its point being entered one-fourth of an inch from the margin, and made to emerge at the junction of the cut surface with the mucous membrane on the

FIG. 435. — Operation of Giraldès. Position of incisions at the margins of the cleft.

FIG. 437. — Operation of Giraldès. Appearance of lip when the operation has been completed.

internal aspect, and then to pass through the lip on the other side in the reverse direction. The second needle is passed in a similar manner at the upper extremity of the cleft, and a third half-way between the two first. Other sutures of fine horse-hair are now passed between the three main sutures, along the other parts of the margins of the cleft, both on the internal and external surfaces. As these are being introduced, the salmon-

gut sutures should be tightened so as to bring the margins of the cleft in exact apposition.

The three salmon-gut sutures are now tied with the first part of the true "surgical knot" (Fig. 45), and the horse-hair sutures

in a reef knot in the usual manner. The ends of all the sutures are cut short.

Some surgeons use silver wire in place of the salmon-gut, but quite as good results can be obtained by the use of salmon-gut, and this substance can be removed much more readily and with less bruising of the tissues. A hare-lip pin is generally quite unnecessary.

(d) *Application of dressing.*—The lips and the margins of the united cleft are carefully washed, so as to remove all traces of

blood and other débris. Then the lip in the region of the wound is gently sponged with a plug of sterilised wool steeped in absolute alcohol.

The spirit is allowed to evaporate, and then a layer of thin gauze, cut in the shape of an hour-glass, placed on the lip and adjacent parts of the cheeks. The surface of this gauze is painted with collodion, which is allowed to dry. A second sheet of gauze is put on, and collodion applied as before. During the time the dressing is being applied the cheeks are pressed forwards by an assistant, and held in that position until the dressing is quite firm.

After-treatment.—The nurse in charge of the patient should be instructed to pull down the lower lip, if necessary, so as to facilitate respiration through the mouth, since it may be impeded owing to narrowing of the nasal apertures.

On the fourth or fifth day the dressing should be removed and the salmon-gut sutures taken out. The margins of the wounds are washed and the dressing re-applied. Three or four days later the dressing is again taken off, all the horse-hair sutures taken out, and a dressing applied which is kept in position by a piece of rubber strapping.

The child will usually be able to suck on the seventh or eighth day, that is, when all the sutures have been removed. Up to this time the milk should be given with a spoon.

(b) **Double hare lip.**—In the operation for the radical cure of a double hare lip, the condition of the intermaxillary bone has much to do with the form of operation and also with the ultimate success. If this bone is very prominent, an attempt may be made to force it backwards, either with or without removal of a portion of the vomerine plate and the nasal septum, after reducing its size by removing the tooth-sacs which it contains. Sometimes the best method is to remove the prominent portion in its entirety, but every case must be considered on its own merits. When the bone has been removed, the maxillæ appear to grow more towards the middle line, until ultimately the space is almost filled up and the cleft in the lip can be readily closed by an operation.

The stages of the operation are similar to those in the single

FIG. 442.—Double hare lip (operation of Maas). Appearance of the lip when the operation is completed.

hare lip; the methods of making the incisions, and the appearances presented when the operations are completed, are shown in Figs. 438-442.

CLEFT PALATE.

A cleft in the palate may involve either a part or the whole of the palatal arch. When the soft palate alone is cleft, the uvula may be simply bifid, or the deficiency may extend as far forwards as the posterior margin of the hard palate. When the hard palate is involved, the portion of the arch which is derived from the palate bones may alone be deficient, or the cleft may extend

FIG. 443.—Mouth gag for use in operations upon the palate.—SMITH.

forwards between the superior maxillæ; while in very extensive cases the cleft passes on one or other side of the premaxillary bones to become continuous with a hare lip. It only very rarely happens that a congenital aperture in the hard palate is met with, unless associated with a similar condition of the soft palate, since the order of closure is from before backwards.

Apertures in the hard or soft palate, usually the latter, may also be dependent upon disease. These usually follow tertiary syphilitic ulcerations of the palatal region. Before attempting to cure an aperture in the palate which has been caused by tertiary syphilis, it is advisable to give the patient a course of anti-syphilitic treatment. Apertures in the soft palate may be cured

by operation, but only in rare instances can perforations in the hard palate be cured.

Period of life at which the operation ought to be performed in cases of congenital origin.—Some surgeons have advocated operation at an early stage, even during the first few months of life; but, according to the experience of most authorities on the subject, the third or fourth year is now considered to be the most favourable time to operate. If the closure of the cleft in the palate is delayed beyond this period, articulation is liable to be interfered with.

When the cleft involves the tissues of both the soft and the hard palate, it is advisable to ensure union of the hard palate first; and if it is possible, the entire cleft should be closed at one operation. When this cannot be done, the cleft in the hard palate should be closed first, and that in the soft portion at a later period.

Special instruments.—Gag, long-handled tenotome or fine-bladed scalpel, ordinary scalpel, scissors (bent and straight), periosteal elevators, long fine-toothed forceps, palate-hook, needles, needle-holder, suture material (fine silver wire, silk, and horse-hair).

Position.—The patient is placed in the dorsal posture on the operation table, with the head raised by a hard pillow. The gag (Fig. 443) is introduced, and the mouth thus held open by an assistant. The surgeon stands on the right side of the patient, the assistant on the left side, and the anaesthetist at the head. The assistant who is administering the anaesthetic usually looks after the gag.

(a) **For cleft of both hard and soft palate.**—The operation may be divided into the following stages, namely—(a) Making of lateral incision, and separation of the muco-periosteal portions of the hard palate; (b) paring of the margins of the cleft; (c) introduction and tying of sutures, and closure of cleft; (d) making of further lateral incisions in order to relieve lateral tension.

FIG. 444.—Operation for cleft palate, complete; the cleft involving both the hard and soft palate.

- a. Position of lateral incisions for division of muco-periosteum.
- b. Position of incision in paring the margins of the cleft.

Operation.—(a) *Lateral incision and separation of muco-periosteum.*—An incision is made through the soft tissues of the palate, commencing at a point internal and opposite to the last temporary molar tooth, and extending forwards parallel with the alveolar margin as far as the anterior border of the canine tooth,—that is to say, just in front of the termination of the cleft, except in those cases in which the deficiency extends

through the alveolus. The palatal tissues should be incised in a direction perpendicular to the surface, and all bevelling of the margins must be avoided.

Care must be taken to divide everything down to the bone, otherwise one or more of the palatine arteries may be only partially divided, and severe hæmorrhage will ensue, which will be difficult to arrest.

Sponge pressure is applied for a short time, and then the muco-periosteal tissues are separated from their connections with the bony palate with the periosteal elevator (Fig. 445).

The separation of these tissues should be extended until the point of the elevator reaches the margin of the cleft. Great care is necessary in effecting the separation of the soft tissues from the region of the posterior part of the hard palate and

FIG. 445.—Periosteal elevator for separation of muco-periosteal flap.

FIG. 446.—Long fine forceps for operations upon palate.

the hamular process, owing to their thinness.

The opposite side is treated in a similar manner, and then the second stage can be commenced.

(b) *Paring margins of cleft.*—With the long forceps one margin of the cleft is seized a short distance in front of the base of the uvula. The tenotome is now taken, made to pass through the palatal tissue opposite the forceps with the cutting

edge looking towards the front, and then a strip of tissue is removed as far as the anterior margin of the deficiency. The line along which this incision is made is shown in Fig. 444. The forward part of the cut having been made, the edge of the knife is turned backwards and the remaining part attached to the uvula cut through. A similar procedure is carried out on the opposite margin of the cleft. An attempt should be made, if possible, to remove the two strips attached to one another anteriorly, so as to ensure that the entire margins have been thoroughly pared.

(c) *Insertion of sutures.*—Many methods of inserting the sutures have been recommended. The sutures of silk or horse-hair must be introduced by some form of needle with an eye, whilst those of silver wire can be most readily introduced by the needle of T. Smith, which is illustrated in Fig. 447. In this needle the stem is hollow, and, after the tissues of the palate have been pierced, the wire is driven through the perforation by turning the wheel which is attached to the handle. A very useful and expeditious method of introducing the sutures is by the small needles and the special form of needle-holder which have been recommended by Lane. These instruments are figured in Fig. 448.

It is best to start from the anterior angle of the cleft in introducing the sutures. When one suture has been inserted, it can be used as a point of support in order to facilitate the insertion of the next one. The sutures which are used to approximate the part of the cleft which corresponds to the hard palate should be of silver wire; and those for the soft palate and the uvula, of horse-hair or fine salmon-gut.

After the sutures have been inserted, the margins of the cleft should be carefully sponged, so as to remove all blood clot, mucus, or other debris. The sutures are now tied and their

FIG. 447.—Tubular cleft-palate needle.—T. SMITH.

ends cut short. In the case of the wire sutures it is best to twist them with the wire-twister shown in Fig. 450, and then to cut the ends short. The uvula is the last portion of the palate to be closed.

FIG. 448.—Needle-holder and small needles for operation upon palate in young children.—ARBUTHNOT LANE.

(d) *Relief of lateral tension.*—The lateral incision on each side is prolonged backwards for a short distance, and the *tensor and levator palati muscles cut through* on the internal aspect of the hamular process. A probe-pointed narrow scalpel is the best for this purpose. When the incision has been made, the wound should be examined, so as to ascertain that the entire muscle has been cut through.

FIG. 449.—Operation for cleft palate. Appearance of the palate when the margins of the cleft have been pared and the sutures have been introduced.

a. Lateral incision.

(e) *For cleft of the soft palate.*—The operation for closure of a cleft which involves the soft palate alone is often known as *staphylorraphy*, that for closure of the hard palate being called *uranoplasty*.

Operation.—The stages of the operation and the manner of its performance are very similar to those in the preceding operation.

In this case, however, it is usual to first pare the edges of the cleft, then to introduce the sutures, and afterwards to make the lateral incision. The lateral incision is placed farther back, and is made to divide the levator palati muscle. The different stages of the operation are illustrated in Figs. 452 to 454.

After-treatment.—Much of the success of the operations for cleft palate depends upon careful attention to the details of the after-treatment. After the operation has been performed, the patient should be placed in bed with his head low, so that any accumulation of blood, mucus, or exudation may pass into the pharynx, and not collect in the immediate neighbourhood of the wound.

No food should be given for the first five or six hours, and only small quantities of milk or milk and soda-water, until all danger of vomiting, as the result of the anæsthetic, has passed off.

After the end of the first day the patient is

FIG. 450.—
Wire-twister.

FIG. 451.—Operation for cleft palate.
Appearance of the palate when the
operation is completed.

a. Space left by separation of margins
of lateral incisions.

fed regularly on a fluid diet. The food can be best administered with a spoon or some form of feeder.

After food has been given, the mouth of the patient should be carefully washed out with a dilute antiseptic, such as a solution of boracic acid or Condy's fluid. In refractory children this cannot as a rule be carried out.

The stitches can usually be taken out from the uvula and the soft palate at the end of a week, and those from the hard palate on the tenth or twelfth day. In young children it is generally advisable to give an anæsthetic before removing the stitches.

It is not advisable to give any form of solid food until after the expiration of two to three weeks.

FIG. 452.—Operation for cleft palate. Partial, involving only the soft palate. The dotted line marks the position where the margins of the cleft are pared.

Many modifications of the operation, especially for closure of the hard palate, have been advocated, but the operation above described will be found to be applicable to the majority of cases.

FIG. 453.—Operation for cleft of soft palate. Appearance of the palate when the margins of the cleft have been pared and the sutures introduced.

FIG. 454.—Operation for cleft of soft palate. Appearance of the palate when the operation is completed.

OPERATION FOR EXTROVERSION OF THE URINARY
BLADDER, OR ECTOPIA VESICÆ.

In ectopia of the urinary bladder the anterior wall is deficient, and most commonly this condition is associated with non-approximation of the pubic bones, and epispadias.

The urine as it is secreted passes along the ureters and escapes through the ureteral openings, which are situated upon the mucous membrane representing the posterior wall of the bladder. This mucous membrane usually projects as a reddened prominence in the hypogastric region.

The condition of a patient suffering from ectopia vesicæ is a very miserable one, on account of the continuous escape of urine and the difficulty which is experienced in fitting up an apparatus which shall collect it as it passes from the ureteral openings.

Patients, however, who have been the subjects of this condition have lived to old age without an operation being performed.

Two varieties of operation may be performed for the relief of extroversion of the urinary bladder. In one class an attempt is made to form a new anterior wall to the bladder, by turning down and reversing a flap of skin from the umbilical region, the epidermal surface of this umbilical flap becoming the lining membrane of the anterior part of the bladder. Lateral flaps are turned up from the inguinal regions, and used for closing in the cutaneous deficiency. This operation is known as the "flap" operation, or "Wood's operation."

In the second class of operation an attempt is made to bring together the anterior extremities of the pubic bones and fix them in apposition, and at the same time the layer of mucous membrane which represents the wall of the bladder is folded upon itself in front, and the margins united in such a manner that a urinary receptacle is formed, the opening of which is situated below and behind the united pubic bones. In order to effect this result, it is usually necessary to divide the sacro-iliac synchondroses behind, and then to force the bones apart in order to approximate the pubic bones in front. The surfaces of these latter bones are freshened and fixed together.

Flap operations.—By a single umbilical flap and two lateral inguinal flaps ("Wood's operation"). A flap of skin and fascia which is pyriform in shape, the narrow portion being above, is reflected from the umbilical region and turned downwards in such a manner that it remains attached by its lower part (Fig. 455, A); the cutaneous aspect is reversed and forms the anterior boundary of the new urinary bladder. The margins

of the mucous membrane of the bladder are refreshed and attached to those of the reversed umbilical flap.

A lateral flap is then taken from each inguinal region ; this is also pyriform in shape, but the attached portion is the narrower (Fig. 455, B and C).

Each of these flaps should consist of skin and superficial fascia. The free extremities are rotated inwards towards the middle line until their inner and upper margins meet ; these are united to one another by the insertion of numerous interrupted sutures. The raw surfaces thus produced are partially closed by bringing the margins of the denuded surfaces together by sutures, the remainder being allowed to close by granulation.

FIG. 455.—Extroversion of the bladder.

Formation of skin flaps.—WOOD.

A Umbilical flap.

B Right inguinal flap,

C Left inguinal flap.

a-b and *a'-b'*.—Bases of inguinal flaps which come together.

It is usually necessary to perform a number of operations before a moderately satisfactory result can be obtained from this form of operation.

The disadvantage of this form of operation is the growth of hair from the cutaneous surface which has been turned inwards.

When this takes place, at puberty or earlier, phosphatic deposits are liable to form, and to give rise to much trouble.

If the mucous membrane which represents the bladder is fairly extensive, an attempt

may be made to free the lateral margins, fold them on themselves, and then unite the approximated borders by the insertion of interrupted sutures. If this can be done, a urinary receptacle is formed which is small in size, but its interior is formed entirely of mucous membrane, and the result is likely to be more satisfactory than in the preceding case.

Operations with division of the sacro-iliac synchondroses and approximation of the separated portions of the pubic bones ("Trendelenberg's operation").—The first stage in this operation includes the making of two incisions over the sacro-iliac synchondroses, division of the posterior ligaments of these joints, forcible separation of the sacrum and iliac bones behind,

and approximation of the pubic bones in front. The surfaces of the pubic bones are freshened with a scalpel before they are fixed together.

In the second stage, which is carried out after the wounds caused by the previous stage have healed, the mucous membrane which represents the urinary bladder is folded upon itself, and its margins united in a manner similar to that described above.

In the third stage, an attempt is made to close in the cutaneous deficiency by the formation of skin-flaps from the groin and lateral margins of the cleft. The inner margins of these flaps are united together in the middle line.

The epispadias which is commonly present in these cases is treated at a subsequent operation.

An objection which has been urged against this form of operation is, that the pelvis is so much weakened by the injury to the sacro-iliac joints that progression is seriously interfered with. This in practice, however, has been found not to be true, since the weakening which takes place posteriorly is in part compensated for by the approximation of the pubic bones in front.

The best result, however, which can be expected in a severe case of extroversion of the bladder is, that it is rendered possible to fit up the patient with an artificial urinal which catches in a satisfactory manner the urine as it is evacuated, and avoids the continual soaking of the clothing.

OPERATION FOR EPISPADIAS.

In the condition of epispadias the penis is cleft along the dorsal surface, and the organ is usually turned towards the abdomen and bent upon itself.

Several operations have been practised for the cure of this condition; the best of these is the following, which is generally known as "Thiersch's operation":—

Operation.—The operation is carried out in four stages, the wounds which have been caused in one stage being allowed to heal before the next stage is attempted.

(a) *First stage: Formation of external urinary meatus, and glandular portion of penile urethra.*—Two incisions are made in the glans penis from each dorso-lateral aspect, as in Fig. 456. These incisions should pass through more than half the substance of the glans penis, and should converge towards one another on the ventral aspect.

The margins of the median portion are pared, and then fixed in approximation by the insertion of several points of interrupted

suture. The middle portion, thus separated, and containing a canal in its interior, is depressed, and the two lateral portions brought together and united by sutures. An aseptic dressing is applied and the wound allowed to heal, the sutures being removed at the end of a week.

FIG. 456.—Epispadias ("Thiersch's operation"). Incisions into substance of glans penis in formation of the meatus.—ESMARCH and KOWALZIG.

(b) *Second stage: Formation of that portion of the spongy urethra which occupies the body of the penis.*—Incisions are made through the skin and fascia on the dorsal aspect of the penis, as in Fig. 457. The incision on the left side is nearer the cleft than that on the right. The two flaps thus marked out are dissected up, and the flap with the attached base close to the cleft is turned over so as to form the roof of the new urethra, and fixed in position. The other flap is then brought over the first one, and fixed by the insertion of sutures (Fig. 458). A catheter is passed along the new urethra and left in position. Dressings are applied and the parts allowed to heal, the sutures being taken out at the expiration of seven or ten days.

FIG. 457.—Epispadias ("Thiersch's operation"). Incision on dorsum of penis.—ESMARCH and KOWALZIG.

(c) *Third stage: Closure of the small interval between the first and second portions of the new urethra.*—The prepuce is brought over the cleft, an incision made through it, and through this the glans penis is passed. The margins of the aperture are freshened, and united to the skin of the prepuce. A sufficient time is allowed for the parts to heal, and then the final stage is undertaken.

FIG. 458.—Epispadias ("Thiersch's operation"). Method of turning over the skin flaps.—ESMARCH and KOWALZIG.

(d) *Fourth stage: Closure of the aperture at the base of the penis, between it and the os pubis.*—This is effected by dissecting up two flaps from the adjacent portions of the inguinal regions. One flap is triangular in shape, and its attached border corresponds to one margin of the orifice which it is wished to close. This flap, after being dissected up, is reversed, and the cutaneous surface made to form the roof of the new urethra. It is fixed in position by the insertion of a number of sutures (Fig. 459).

Next, a rectangular-shaped flap is dissected up from the other inguinal region. It is brought over the first flap in such a

manner that the two raw surfaces are in approximation. The margins are then united by sutures.

A catheter is passed along the entire urethral canal as thus completed, and allowed to remain until union has taken place.

It is advisable that this catheter should be changed daily after the first twenty-four hours.

In order to obtain a good result from this operation, it is advisable to allow plenty of time to elapse between the individual stages, and if one stage fail, to repeat this before going on to the next.

OPERATION FOR HYPOSPADIAS.

In the condition of hypospadias there is a cleft on the under surface of the penis; this may involve the meatal region alone, or any portion of the spongy portion of the urethra as far back as the perineum.

The slighter malformations of this nature scarcely require surgical treatment; but when the penile part of the urethra is cleft or the scrotum involved, an operation should be attempted for the rectification of the deformity.

Usually the penis is small and deformed, and is bent towards the scrotum, a fibrous band often holding it down.

If an operation is considered advisable, it should be carried out during early childhood, before the fifth or sixth year.

The form of operation which is recommended is that described by Duplay.

Special instrument.—Catheter.

Position.—The patient is placed in the dorsal position on the operation table, the thighs being separated; or, if the scrotum is involved, in the lithotomy position. The surgeon stands on the right side of the patient and the assistant on the opposite side.

Operation.—The operation may be divided into the following stages, namely—(a) Straightening the penis; (b) formation of an external urinary meatus; (c) formation of a urinary canal;

FIG. 459. — Epispiadias ("Thiersch's operation"). Closure of fistula between original and newly-formed portions of the urethra.—ESMARCH and KOWALZIG.

and (d) closure of the fistula at the junction of the new-formed canal and the termination of the original urethra.

(a) *Straightening the penis.*—This is effected by making one or more transverse cuts through the fibrous band which fixes the under surface of the penis to the scrotum. It is often necessary to extend these incisions into the substance of the corpora cavernosa.

(b) *Formation of an external meatus.*—An incision parallel with the long axis of the penis is made on each side of the groove which represents the urethral canal on the under surface of the glans penis. A catheter is placed in the groove, and the tissues at the inner margin of each incision are turned inwards over the catheter and fixed thus by the insertion of sutures. Next, the tissues at the outer margins of the incisions are freed for a short distance and brought over the new meatus, and sutured in this position.

The straightening of the penis and the formation of the meatus are performed at the same time. Sufficient time is allowed for these wounds to heal, and then the next stage is carried out.

(c) *Formation of a urinary canal.*—A catheter is passed through the new meatus and along the groove on the under surface of the penis into the original opening of the urinary canal. An incision parallel with the catheter is then made on each side of the groove and a short distance from it, and a small transverse incision along each extremity of the long one. A small flap is then dissected up for a short distance on each side, and turned over the catheter in such a manner that the cutaneous surface lies in contact with it. It is not necessary that the margins of these two flaps should be in apposition over the catheter. The tissues at the external margin of each longitudinal incision are next dissected up very freely until these margins can be brought into approximation on the ventral aspect of the catheter, which lies in the urethral groove. The approximated borders of the external flaps are fixed in apposition by the insertion of a series of interrupted sutures.

A sufficient time is now allowed to elapse until the flaps thus united have become quite healed.

(d) *Closure of the fistula between the distal extremity of the old urinary canal and the proximal extremity of the new one.*—The margins of the fistulous aperture are pared, and if necessary a flap of skin is dissected up from the adjacent portion of the penis. This is brought over the aperture and fixed by sutures.

SKIN GRAFTING.

This procedure may be requisite in cases of extensive destruction of the skin, the result of a burn or scald, of some form of injury or ulceration, or of a surgical operation carried out for the removal of a malignant growth.

Skin grafting by the ordinary method.—

The surface upon which the grafts are to be placed is first rendered as aseptic as possible by fomentations or other measures; then, with a pair of fine forceps and scissors, small portions of the skin are removed by sharp snips from a healthy cutaneous surface, and placed upon the prepared surface. Each graft of skin should be about one-sixth of an inch wide, and should include both the epidermis and the superficial part of the dermis.

These grafts are placed at equal distances apart, usually about one-third or one-half inch from each other. A perforated piece of aseptic oiled silk is then placed over the grafted area, and an aseptic dressing applied. The wound thus treated should not be disturbed for several days, unless there is much exudation from its surface.

When the dressings are removed, the surface should be very gently washed, or sponged and dried, and then a similar dressing applied.

Skin grafting by "Thiersch's method."—

The essential point in this method of skin grafting is the transference of large sheets of epidermal tissue from a healthy part to the surface of the wound which has lost its cutaneous covering.

The strips of epidermis should measure 1 or $1\frac{1}{2}$ in. in width, and from 2 to 3 in. in length. They can be most readily obtained from the internal aspect of the thigh.

A special instrument, known as Thiersch's knife (Fig. 460), is used for the purpose of making these epidermal strips.

The skin of the area from which it is proposed to obtain the

FIG. 460.—Skin grafting. Thiersch's knife.

epidermal strips is rendered aseptic in the usual manner. Then the blade of the knife is moistened with normal saline solution at the temperature of the body, and a thin shaving made, the blade of the knife being held on the flat. Each strip should consist of the epidermis and the apices of the underlying papillæ; it ought to be not less than half an inch wide, and 2 in. or more long. Care must be taken not to injure the subepidermal tissues in obtaining the epidermal strips.

When a strip of epidermis has been obtained it is placed on the prepared surface, and when the whole raw surface has been covered, dressings are applied as in the previous case.

When the surface which is to be grafted is granulating, the granulations should be scraped away with a spoon before the epidermal strips are placed upon it. In every case the area to be grafted must be rendered as aseptic as possible before the transference of the grafts is carried out, and hæmorrhage should be completely arrested.

CHAPTER XXX.

OPHTHALMIC OPERATIONS.

BY WALTER H. JESSOP, M.B., F.R.C.S.,

*Senior Ophthalmic Surgeon to, and Lecturer on Ophthalmology
at, St. Bartholomew's Hospital.*

General considerations.—The main details of the anæsthetic employed, the preparation of the eye, and the position of patient and operator, are, as a rule, the same in all ophthalmic operations, and will be stated here, to prevent repetition under the different operations.

The anæsthetic used is generally cocaine, which can be applied easily, and induces sufficient anæsthesia of the cornea, conjunctiva, and even iris, to allow most operations to be performed painlessly with it.

Cocaine is best employed as a 2 to 4 per cent. solution, and must be used fresh, owing to its solutions keeping badly. It should be dropped into the eye three or four times before the operation; a good rule to observe is to begin the first instillation ten minutes before the operation, to repeat it again in five minutes, then for the third time just before the speculum is introduced, and for the fourth time after the eye has been washed out. If the iris is to be cut, cocaine should be instilled again immediately after the corneal incision, so that it may be directly applied to the iris. The slight disadvantages of cocaine are—that intra-ocular tension is diminished, the cornea rendered flaccid and more difficult to cut, and from this flaccidity there is a greater difficulty in extrusion of the lens in cataract extraction.

Cocaine is contra-indicated in inflamed eyes, glaucoma, tenotomy in young and nervous patients, and excision.

Of general anæsthetics, chloroform is preferable to ether, but the grave objection to general anæsthetics is their tendency to make patients vomit, and from the straining thereby induced intra-ocular hæmorrhage may afterwards result.

The operations hereafter described are best performed with the patient lying on his back on a table in a good light, and the operator standing behind his head. The only exception to this rule is tenotomy, when the operator stands in front and on the right side of the patient. If the surgeon be unable to operate with either hand, it is necessary for him, in cases of extraction on the left side, to stand in front and to the left of the patient.

The assistant, when one is required, should stand at the side of the patient.

Owing to the communication of the nasal passage with the conjunctival sac by the canaliculi and puncta, it is impossible to ensure asepsis for more than a short time. It is important, however, that the eye should be well cleansed before the operation. This is best done by carefully washing the lids and eyelashes with boracic acid solution, and then syringing out the conjunctival sac with the same, or with distilled and sterilised water.

When the operation is finished, the eye must be again irrigated before the bandage is applied.

All instruments, except the knife, are to be boiled for twenty minutes. The knife should be dipped into absolute alcohol before being used.

All knives, needles, and scissors should be tested at the time of operation, as to their cutting or perforating powers, on a piece of thin kid leather. A convenient way is to stretch the leather over a small ivory cylinder, thus making a drum.

The following operations are all described as taking place on the right eye; the only change necessary, when operating on the left side, is the transposition of

left for right in the description.

Slitting up the canaliculus.—The operation for slitting up the canaliculus is generally performed on the lower canaliculus.

Indications.—The operation is practised for the cure of “watery eye” (epiphora), caused by obstruction or misplacement

FIG. 461.—Canaliculus knife.—WEBER'S.

of the lachrymal drainage system (punctum, canaliculus, and nasal duct).

Instruments.—A probe-pointed canaliculus knife (Weber's), Fig. 461), small fixation forceps, and a pair of small scissors.

Operation.—The operator, standing behind the patient, draws down and outwards the lower lid by means of a finger, so as to expose the punctum. If the latter be very small, it must be dilated by small probes until the probe-point of the knife can be introduced. The probe-point of the canaliculus knife is passed vertically into the punctum, and, the handle being lowered, the point is passed horizontally onwards along the canaliculus until the end of the knife is felt to touch the inner surface of the nasal sac. The knife is then raised forwards and upwards, its handle describing an angle of 90° , till it becomes parallel with the nose: by this means the canaliculus is laid open as far as its entrance to the nasal sac. Any blood is sponged away, and the mucous membrane at the inner or posterior border of the incision is seized with the forceps, and a small strip of it cut off, so as to prevent the wound healing too soon.

It is usual, after slitting up the canaliculus, to pass a lach-

FIG. 462.—Lachrymal probe.

rymal probe down the nasal duct, to be sure that there is no obstruction.

Passage of lachrymal probe down the nasal duct.—The probe (Fig. 462) should be introduced into the lower punctum nearly at right angles to the border of the lid; its outer extremity then being depressed, the probe is passed horizontally along the canaliculus till its point is felt to touch the inner mucous surface of the lachrymal sac. The probe is now raised, with its end still touching the mucous membrane of the sac, till it becomes parallel to the nose, and the lower end, which should be now over the entrance to the nasal duct, is pushed downwards and slightly backwards and outwards; it should then glide gently into the duct without the employment of any undue force.

The duct may be dilated quickly at one sitting by passing probes of increasing sizes, or a style may be introduced and left in.

Tenotomy.—Tenotomy in ophthalmic surgery denotes the division of one of the extrinsic ocular muscles. Since conver-

gent and divergent strabismus are the most frequent forms, the internal and external recti are the muscles which generally require division.

Indications.—The presence of squint which is not amenable to other methods of treatment.

Instruments.—Speculum, fixation forceps, blunt-pointed curved scissors, strabismus hook.

Operation.—The operator, standing in front and on the right

FIG. 463.—Fixation forceps.

FIG. 464.—Curved scissors.

FIG. 465.—Spring speculum.

side, having introduced the speculum (Fig. 465), fixes the conjunctiva and subconjunctival tissue with the fixation forceps (Fig. 463), at the point of junction of the lower horizontal and inner vertical tangents of the cornea. The fold of conjunctiva thus pinched up is divided in the direction away from the cornea with a pair of blunt-pointed scissors (Fig. 464) to such an extent as will admit the points of the scissors, which are passed

through the opening, and divide the capsule of Tenon beneath the conjunctival incision.

The hook (Fig. 466) is now introduced into the wound with the point directed backwards: the point is then turned upwards between the globe and the tendon until it appears beneath the conjunctiva at the upper border of the tendon, which is in this way brought forwards. The scissors are now introduced into the wound, and the blades are opened on either side of the tendon, between the hook and the globe, and the tendon is cut through. The hook is removed and again introduced to try if the tendon has been completely divided; if not, the scissors must be again employed.

The eyes should be bandaged up for twelve hours.

The above description applies to the division of the internal rectus; the method of dividing the external rectus is similar, but it must be remembered that the latter tendon is inserted farther back.

Advancement of a muscle.—In cases of strabismus, instead of dividing a tendon, as for example the internal rectus, for internal squint, the insertion of the opposing muscle, in this case the external rectus, may be advanced.

Indications.—Usually to increase the effect of a tenotomy, especially when there is a marked limitation of the movements of the eye in the direction of the proposed operation.

Instruments.—Speculum, fixation forceps, tenotomy hook, scissors, three needles threaded with thin silk.

Operation.—The operation here described refers to the right external rectus.

The speculum (Fig. 465) being introduced, the operator seizes the conjunctiva with fixation forceps, opposite the middle of the insertion of the external rectus about $\frac{1}{4}$ in. away from the corneal border, and divides it vertically with a pair of scissors

FIG. 466.—Strabismus hook.

above and below the point of fixation, to the extent of about a quarter of an inch. The subconjunctival tissue and the capsule of Tenon being divided to the same extent, the tenotomy hook (Fig. 466) is passed from below beneath the muscle, and its point brought out at the upper border of the muscle; the tendon by this means is exposed lying on the hook.

A suture is now passed through the tendon on the outer side of the tenotomy hook, and the needle is made to perforate the episcleral tissue and the conjunctiva at the level of the middle of the cornea, in the proposed fresh situation of the attachment of the tendon. This suture may simply be used as a temporary one, to give the required direction to the advanced muscle. The muscle is now divided close to its insertion, and if thought necessary a piece may be removed from the tendon to shorten it, care being taken not to divide the suture at the same time. The suture is now tied tight. A second suture is introduced into the upper part of the tendon, and this in the same manner is passed through the episcleral tissue and conjunctiva, and should lie above and parallel with the original suture. A third suture is passed through the lower part of the tendon in a similar manner, lying parallel with the preceding ones.

The second and third sutures are now tied, and the first may be removed if desired.

The conjunctival wound is stitched up, and, the speculum being removed, the eye is washed out, and both eyes are bandaged up.

The bandages are kept on for a week, and the stitches allowed to work their way out.

Paracentesis.—Paracentesis is the operation of tapping the anterior chamber by puncturing the cornea, and is performed for the purpose of evacuating the contents of the anterior chamber in cases of high tension, hypopyon, and threatening perforation from ulceration or other cause.

Instruments.—Speculum, fixation forceps, keratome or broad bent cutting needle, and curette.

Operation.—The operator having introduced the speculum between the lids, steadies the eye by fixation forceps, and passes the keratome (Fig. 467) or the bent needle through the lower part of the periphery of the cornea into the anterior chamber, and thus lets out the aqueous humour. If the aqueous does not escape readily, it may be necessary to press with a curette on the lower lip of the wound to enable it to do so.

After the operation it is very important to be sure that the iris is in place, as otherwise prolapse may result.

Iridectomy.—Iridectomy is the operation for the removal of a portion of the iris.

Indications.—The operation is undertaken—(a) To improve sight in cases of corneal opacity, lamellar cataract, and anterior polar cataract; (b) as a remedial measure in glaucoma, relapsing iritis, complete posterior synechia, and injury; (c) during the operation of cataract extraction, either at the same time or as a preliminary proceeding.

Instruments.—Speculum, fixation forceps, keratome, iris forceps, iridectomy scissors, and a curette or spatula.

Operation.—The speculum being introduced between the lids, the operator fixes the conjunctiva gently and firmly, about 1 mm. from the corneal edge opposite the seat of the proposed incision, with a pair of fixation forceps (Fig. 463) held in the left hand.

Taking the keratome (Fig. 467) in the right hand, he passes it by pressure through the periphery of the cornea into the anterior chamber parallel to the iris. He now lowers the handle a little until the point of the keratome nearly touches the posterior surface of the cornea, so as to avoid wounding the lens. As soon as the corneal wound is large enough, the keratome is slowly withdrawn and the aqueous escapes, often followed by the iris.

The fixation forceps, still attached to the conjunctiva, are now given to an assistant to depress the eye, and the operator passes the iris forceps (Fig. 469) through the corneal wound, with their points closed and directed towards the posterior surface

FIG. 467.—Keratome.

FIG. 468.—Curette and cystotome.

of the cornea; the points are then opened, and the pupillary border of the iris seized between them; the piece of iris is slowly and carefully drawn out, and cut off with the iridectomy scissors (Fig. 470). This may be done either parallel to the wound or at right angles to it across the cornea. The edges of the cut iris are carefully returned with a curette (Fig. 468), the operator making sure that the pupillary margin on both sides is in position.

FIG. 469.—Iris forceps.

FIG. 470.—Iridectomy scissors.

The eye is now bandaged up, and in a simple case of iridectomy the bandage may be discontinued in forty-eight hours, if the anterior chamber is re-formed and the eye not irritable.

Modifications of iridectomy.—(a) The operator may make the corneal section with a Graefe's knife (Fig. 472) instead of the keratome. In such a case he would introduce the knife through the periphery of the cornea at a point corresponding to one edge of the coloboma which he intends to produce. The knife is then passed across the anterior chamber, and transfixes the cornea at a point corresponding to the other edge of the coloboma. The succeeding steps of the operation are similar to those given above.

(b) In iridectomy for glaucoma, the patient should, as a rule, be under a general anæsthetic. The operation may be done with a keratome, but most surgeons prefer a Graefe's knife. The operator introduces the knife through the sclerotic about 1 mm. from the apparent corneal margin, and about the junction of the upper one-sixth with the lower five-sixths of the cornea. The knife is then passed across the anterior chamber with great care (so as not to wound the iris), and makes a counter-puncture in the sclerotic at a corresponding point on the opposite side. The knife is then made to cut its way through the sclerotic,

producing an arc in this structure parallel to the curve of the cornea. The iris is seized with a pair of iris forceps at one edge of the section, and drawn out; it is then cut with the scissors and torn across to the opposite edge of the wound, where it is again cut by scissors.

Sclerotomy.—By the term “sclerotomy” is understood, division of the sclera beneath the conjunctiva.

Indications.—The operation is performed for the relief of glaucomatous symptoms; it is probably only useful and successful, as a secondary operation, after iridectomy has been performed some time before.

Instruments.—Speculum, fixation forceps, and Graefe’s knife.

Operation.—The operator, standing behind the patient, seizes the conjunctiva below the lower margin of the cornea with the fixation forceps held in his left hand. Taking the Graefe’s knife (Fig. 472) in the right hand, he enters it at a point in the sclerotic 1 mm. from the corneal margin, as in the operation of iridectomy for glaucoma, and at the junction of the upper one-sixth and lower five-sixths of the cornea.

He now passes the knife across the anterior chamber in a horizontal direction, with its cutting edge upwards, and makes a counter-puncture in the sclera at a point corresponding to the original one on the other side. The knife is made to cut its way upwards, until a small bridge of sclerotic is left above undivided, and is then slowly withdrawn.

A bandage is now placed over the eye and kept on for twenty-four hours.

Extraction.—Extraction is the operation for removal of the lens. The operations for extraction are numerous, so far as details are concerned; the one most often practised now, and described below, is the “three-millimetre corneal flap” operation. It may be performed with or without an iridectomy.

“Three-millimetre corneal flap” operation with iridectomy.—*Instruments.*—Speculum, fixation forceps, Graefe’s knife, iris forceps, iridectomy scissors, cystotome, and curette.

Operation.—The speculum is introduced between the lids, and the operator, holding the fixation forceps in his left hand, fixes the conjunctiva in the middle line below and 1 mm. from the

FIG. 471.—
Stop-needle.

corneal edge. Holding the Graefe's knife lightly between the thumb and first two fingers of the right hand, he introduces the point of the knife on the outer side, just within the corneal margin, at a distance of 3 mm. from the highest point of the cornea. The knife is then passed across the anterior chamber, in front of the iris, to a point within the periphery of the cornea on the nasal side, exactly corresponding to the original puncture, so that the knife on making the counter-puncture lies in a horizontal line with the cutting edge upwards.

The knife is now made to cut its way upwards in the cornea by slow to-and-fro movements, until the upper margin of the cornea is reached and cut through. The aqueous humour has now all escaped, and the whole section will be found to be in the cornea and corresponding to its curve.

Iridectomy stage.—The patient is now directed to gaze at his own hand raised slightly above the level of his body, in order to depress the eyeball; if he cannot be trusted to keep quiet, the conjunctiva must be held by fixation forceps, which are entrusted to an assistant.

The operator, introducing the iris forceps (Fig. 469) through the highest point of the incision, seizes the iris by its pupillary border, and slowly withdraws it through the centre of the wound; he then cuts off the portion withdrawn by means of iridectomy scissors (Fig. 470) held in his right hand.

Next, a cystotome (Fig. 468) is introduced, and by its means the upper part of the lens capsule is gently but freely lacerated. The patient is directed to look downwards, whilst moderate pressure is made by a curette held in the right hand, below the lower border of the cornea, till the upper edge of the lens presents itself in the wound; this pressure being kept up gradually, the lens is delivered. It assists the process of delivery of the lens, to take a small flat spatula in the left hand and apply it along the upper border of the wound, so that the lens is delivered over the spatula. After delivery of the lens, any débris remaining must be coaxed out by pressure, by the curette from below, until the pupil assumes a black colour. The edges of the iris must now be pushed in by the curette, so as to ensure their not being caught in the wound.

The "three-millimetre corneal flap" operation without iridectomy.—The instructions are the same as above until the corneal incision is made; the description of the iridectomy stage is to be left out, and the details of the operation resumed at the introduction of the cystotome. After the lens has been extruded, it is necessary to return the iris, which has prolapsed, by means

of a spatula, and to make sure that the pupil is round and not too large. This is best effected by rubbing the centre of the cornea with the spatula; a drop of eserine will quicken the contraction of the pupil. If, however, the pupil cannot be rendered round, or the iris is caught in the wound, an iridectomy must be performed.

After-treatment.—It is customary to bandage both eyes so as to procure rest after the operation. The eye which has not been operated upon may be uncovered after the fourth day, but it is usual to keep the operated-on eye covered for at least a week, to ensure firm union of the wound.

Atropine drops are used after two or three days, if the operation has been done without iridectomy; some surgeons use it after all extraction operations.

After two months the vision should be tested for glasses, and if it is good, glasses may be ordered, a weaker pair for distance and a stronger for near objects, as reading.

After-cataract.—In many cases, after extraction has been performed, the capsule left becomes opaque, giving rise to the so-called “after-cataract.”

The operation for after-cataract is performed as follows:—

The eye being under the influence of atropine and cocaine, a speculum is introduced by the operator, who fixes the eyeball with forceps, and passes a needle (Fig. 471) through the periphery of the cornea from above, and breaks up the opaque capsule. Sometimes it is necessary to use two needles.

Discission.—This operation consists in the laceration of the anterior capsule and substance of the lens with a needle, so as to allow the aqueous humour access to the lens substance for the purpose of inducing absorption.

Indications.—Discission is performed in some forms of lamellar, congenital, and traumatic cataracts. Lately it has been practised in order to produce absorption of the lens in cases of high myopia.

Instruments.—Speculum, fixation forceps, and a cataract needle.

Operation.—The pupil having been fully dilated beforehand by atropine, the operator introduces the speculum, and fixes the conjunctiva below the lower margin of the cornea with the fixation forceps held in either hand.

The needle (Fig. 468) is then firmly, gently, and slowly pushed through the cornea near its periphery, preferably above, until its point traverses the anterior chamber and reaches the middle of the pupil. The handle of the needle being raised, the point

is made to tear through the anterior capsule of the lens near its centre; the needle is now slowly withdrawn.

Atropine is again instilled into the conjunctival sac, and the eye bandaged up for at least twenty-four hours.

This operation has generally to be repeated once or twice.

If the stirred-up lens matter does not tend soon to become absorbed, or, owing to swelling of the lens, glaucomatous symptoms are produced, it is necessary to evacuate the lens débris.

This is done by making a corneal incision, preferably below and on the nasal side, with a keratome (Fig. 467) or bent needle, as described under "Paracentesis" (p. 638). After the aqueous is let out, a curette (Fig. 468) is introduced through the wound, and by manipulating the curette the soft lens matter passes along its groove, and is thus removed.

If afterwards any portion of the capsule remains in the pupil and obstructs vision, the operation for after-cataract (p. 643) must be performed.

Convex glasses are ordered for distance and for reading, after all inflammatory symptoms have subsided.

Excision.—Excision is the operation for complete removal of the eyeball.

Indications.—Rupture of the globe, presence of a foreign body, old painful blind eyes, and malignant growths.

Instruments.—Speculum, fixation forceps, tenotomy hook, and curved blunt-pointed scissors.

Operation.—The operator having introduced the speculum between the lids, fixes the conjunctiva at the inner or outer border with the fixation forceps, and divides the conjunctiva and subconjunctival tissue as close as possible to the corneal margin by means of the scissors (Fig. 464). The hook (Fig. 466) is introduced, and each rectus tendon in succession is raised by it, and divided on the ocular side of the hook close to the eyeball, with the ex-

FIG. 472.—
Graefe's
knife.

ception of the external rectus, which is cut on the orbital side of the hook, and this part of the tendon left attached to the eyeball. It is best, after section of the recti tendons, to sweep the hook round the eyeball, and thus make certain of their division being complete.

The ocular attachment of the external rectus is now seized firmly with the fixation forceps, and the eyeball is rotated inwards and drawn forwards.

The scissors, held in the right hand, are now passed from the outer side with the points closed, and are employed to feel for the optic nerve. When this structure is felt, the scissors are opened and the nerve divided as far back as possible.

The globe is pulled forwards with the fixation forceps, and the attachments of the oblique muscles and a portion of the capsule of Tenon divided, together with vessels and nerves, by the scissors.

The globe is now free from its connections, and can be removed. After the operation, the socket is washed out and a pad and bandage applied.

Hæmorrhage may be profuse, but can always be checked by pressure.

When the bandages are left off, after four or five days, it is advisable to place in the socket every day a pledget of absorbent cotton-wool soaked in oil. This pledget prevents inversion of the lashes, and also prepares the conjunctival sac for the insertion of the artificial eye.

After two to three months an artificial eye may be ordered; it is better that the first eye should be smaller than the permanent one.

INDEX.

- ABDOMINAL AORTA, ligature of, 402.
 section, 42.
 Abernethy's operation for ligature
 of the external iliac artery, 406.

- volsellum, 365.
- Waring's, 350.

Forearm, amputation through, 551.

Foreign bodies, extraction of, from external auditory meatus, 356.

Fracture, ununited, operations for, 476.

Frank's method of gastrostomy, 55.

Frontal sinuses, exploration of, 350.

GAG, Ackland's, 303.

Smith's, 618.

Ganglion, Meckel's, excision of, 439.

Gasserian, excision of, 439, 442.

Gastric ulcer, perforated, operation for, 74.

Gastrectomy, 61.

Gastro-enterostomy, 70.

Gastrostomy, 50, 53.

Gastrotomy, 57.

Gauze, tampon of, 40.

Genital organs—

- operations upon female, 228.
- caruncle, removal of, 228.
- colporrhaphy, 238.
- colpotomy, 240.
- hysterectomy—
- abdominal, 249.
- vaginal, 247.
- for imperforate hymen, 228.
- for ruptured perineum, 229.
- for recto-vaginal fistulæ, 237.
- for vesico-vaginal fistulæ, 236.
- ovariotomy, 250.

Genital organs—

operations upon female—

salpingo-oophorectomy, 255.

on the vagina, 234.

operations upon male, 218.

amputation of penis, 219.

castration, 223.

circumcision, 218.

for epispadias, 627.

hydrocele, radical cure of, 224.

for hypospadias, 629.

for varicocele, 225.

Giraldès's operation for single hare lip, 615.

Gland, thyroid, operations on, 295.

Glands, lymphatic, removal from axilla, 601.

Gloves, rubber, 17.

Gluteal artery, ligature of, 423.

Gorget, Teale's, 212.

Gottstein's curette, for removal of adenoid growths, 351.

Gould's operation for amputation of penis, 222.

Graefe's knife, 644.

Great occipital nerve, exposure of, 447.

sciatic nerve, exposure of, 452.

Gritti's amputation through condyles of femur, 591.

Gussenbauer's artificial larynx, 275.
suture, 46.

HÆMORRHAGE, arrest of, 33.

Hæmorrhoids—

operations for, 107.

crushing, 109.

excision, 109.

ligature, 107.

Hahn's tracheotomy tube, 301.

Halsted's quilted or mattress suture, 47.

operation for removal of breast, 606.

Hands, cleansing of, 16.

Hare lip—

operations for, 612.

single, 612.

double, 617.

Heart, treatment of wounds of, 289.

Hepatectomy, 145.

Hepatotomy, 141, 143.

Hernia—

director, 138.

knife, 139.

Hernia—

needle, Macewen's, 129.

operations for, 118.

for radical cure, 119.

femoral, 119.

inguinal, 119, 122, 123, 124,

125, 126, 128.

umbilical, 119.

for relief of strangulation, 136.

femoral, 139.

inguinal, 136.

obturator, 140.

umbilical, 140.

Hey's amputation through tarso-metatarsal joint, 572.

saw, 270, 334.

Hip-joint—

amputation through, 595.

excision of, 512.

Hook, blunt, 437.

Horsley's periosteal elevator, 317.

Howse's knee-splint, 518.

Hydrocele, radical cure of, 224.

Hypospadias, operation for, 624.

Hysterectomy, 249.

abdominal, 249, 256.

vaginal, 247.

ILIAC arteries—

ligature of common, 403.

external, 405.

internal, 421.

Imperforate rectum, 118.

Incision, appearance of, 37.

closure of, 36, 37.

with sutures, 45.

Inferior maxilla, excision of, 482.

Infra-orbital nerve, exposure of, 438.

Inguinal colotomy, 101.

hernia—

operations upon, for radical cure, 119.

Bassini's operation, 124.

Kocher's operation, 127.

Macewen's operation, 129.

for relief of strangulation, 136.

Innominate artery, ligature of, 372.

Instruments, list of, 5.

selection of, 4.

sterilisation of, 5.

Intercostal arteries, ligature of, 401.

Internal carotid artery, 401.

ligature of—

carotid artery, 385.

iliac artery, 421.

Internal carotid artery—

ligature of—

jugular vein, 425.

mammary artery, 390.

pudic artery, 422.

Interphalangeal joints, excision of,

of foot, 523.

of hand, 512.

Intestinal clamp, 71.

suture, methods, 44.

Intestines—

operations upon, 49.

large intestine, 49, 91.

excision of cæcum, 98.

inguinal colotomy, 101.

lumbar colotomy, 105.

removal of vermiform ap-
pendix, 91.

resection of colon, 100.

small intestine, 76.

closure of perforating wound,
76.

formation of artificial anus, 88.

removal of portion, 77.

resection, 79.

Intubation of larynx, 275.

Intussusception, 100.

Irrigation of peritoneal cavity, 43.

JAW, lower, excision of, 482.

upper, 479.

Joints—

excision of, 498.

ankle, 520.

elbow, 503, 506.

hip, 512.

interphalangeal, foot, 523.

hand, 512.

knee, 515.

metacarpophalangeal, 511.

metatarsophalangeal, 523.

radio-ulnar, 507.

shoulder, 501.

temporo-maxillary, 523.

wrist, 508.

Jordan's, Furneaux, amputation at
hip-joint, 595.

Jugular vein, internal, ligature of, 425.

KIDNEYS—

operations upon, 168.

nephrectomy, 174.

nephrolithotomy, 168.

nephrorrhaphy, 178.

nephrotomy, 173.

Knee-joint—

amputation through, 581.

excision of, 515.

Knife—

amputating, long, 32.

short, 577.

bistoury, 110.

for incision of membrana tympani,
359.

Graefe's, 644.

keratome, 639.

resection, 500.

ring-shaped, for adenoids, 351.

scalpel, 30.

Thiersch's, 631.

methods of holding, 30, 31.

Knots, methods of tying, 38.

Kocher's operation—

for excision of elbow-joint, 507.

for radical cure of inguinal hernia,
127.

for removal of tongue, 307.

Kraske's operation for excision of
rectum, 115.Krönlein, ligature of middle men-
ingeal artery, 384.

LACHRYMAL probe, 635.

Laminectomy, 334.

Lane's cleft palate needles and
needle-holder, 622.Large intestine, operations upon
(see Intestines), 91.

Laryngotomy, 268.

tube, 270.

Laryngo-tracheotomy, 281.

Larynx—

artificial, 275.

operations upon, 268.

intubation of larynx, 275.

instruments, 276.

laryngectomy, 272.

laryngotomy, 268.

laryngo-tracheotomy, 281.

thyrotomy, 270.

Lateral lithotomy, 204.

sinus, exposure of, 426.

Le Fort's amputation of foot,
580.

Leg, amputation through, 581.

Lembert's suture, 44.

Lengthening of tendons, 465.

Ligaments—

operations upon, 464.

- Ligaments—**
 operations upon—
 division of astragalo-scaploid ligament, 464.
- Ligature of arteries** (*see* Arteries, ligature of), 367.
 of veins (*see* Veins, operations upon), 425.
- Lingual artery, ligature of**, 379.
 nerve, exposure of, 445.
- Lion forceps**, 481.
- Lisfranc's amputation through tarso-metatarsal joint**, 571.
- Litholapaxy**, 195.
- Lithotomy—**
 forceps, 202.
 knife, 206.
 lateral, 204.
 median, 206.
 staff, 204.
 suprapubic, 199.
- Lithotrite**, 197.
- Lithotripsy**, 195.
- Liver—**
 operations upon, 141.
 exposure of upper surface by transthoracic operation, 144.
 hepatectomy, 145.
 hepatotomy, 141-143.
- Lower jaw, excision of**, 482.
- Lumbar colotomy**, 105.
- Lungs—**
 operations upon, 281.
 excision of empyema cavity, 285.
 incision of pleura, 284.
 pneumotomy, 281.
 T-shaped tube, 285.
- Lymphatic glands, axillary, removal of**, 603.
- MAAS, operation for double hare lip**, 617.
- Macewen's method of osteotomy of femur**, 468.
 operation for radical cure of inguinal hernia, 129.
 hernia needles, 129.
 osteotome, 469.
- Mackenzie's tonsil guillotine**, 364.
- Malgaigne's operation for single hare lip**, 614.
- Mallet**, 320.
- Mammary gland—**
 operations upon, 599.
 for mammary abscess, 599.
- Mammary gland—**
 operations upon—
 removal of non-malignant tumours and cysts, 601.
 removal of breast, 601.
- Mastoid antrum and cells, exploration of**, 360.
- Mattress suture, Halsted's**, 57.
- Maunsell's method of intestinal anastomosis**, 82.
- Maxilla, inferior, excision of**, 482.
 superior, excision of, 479.
- Maydl and Reclus, method of inguinal colotomy**, 103.
- Meckel's ganglion, removal of**, 439.
- Median nerve, exposure of**, 451.
- Membrana tympani, incision of**, 359.
- Metacarpal bones, excision of**, 488.
- Metacarpo-phalangeal joints—**
 amputation through, 545.
 excision of, 511.
- Metatarsal bones, excision of**, 497.
- Metatarso-phalangeal joints—**
 amputation through, 567.
 excision of, 523.
- Metatarsus, amputation through**, 569.
- Meyer's ring knife**, 351.
- Middle meningeal artery, ligature of**, 383.
- Murphy's button—**
 for intestinal anastomosis, 84.
 for cholecyst-enterostomy, 157.
- Muscles, operations upon**, 455.
- Musculo-spiral nerve, exposure of**, 448.
- Myoma screw, Doyen's**, 261.
- NARES, plugging of**, 345, 346.
- Nasal plugs, Walsham's**, 344.
 forceps, 343.
 polypi, removal of, 341.
 septum, deviated, rectification of, 344.
 speculum, 342.
 wire snare, 343.
- Naso-pharyngeal polypi, removal of**, 347.
- Needle-holders**, 36.
- Needles**, 35.
- Nélaton's operation for single hare lip**, 613.
- Nephrectomy**, 174.
 abdominal, 177.
 lumbar, 174.

Nephrolithotomy, 168.

Nephropexy, 178.

Nephrorrhaphy, 178.

Nephrotomy, 173.

Nerves—

operations upon, 433.

exposure of special nerves, 438.

anterior crural, 453.

tibial, 453.

auriculo-temporal, 444.

brachial plexus, 447.

facial, 445.

Gasserian ganglion, 439.

great occipital, 447.

sciatic, 452.

infra-orbital, 438.

lingual, 445.

Meckel's ganglion, 439.

median, 451.

musculo-spiral, 448.

peroneal, 453.

popliteal, 453.

posterior tibial, 453.

spinal accessory, 446.

supra-orbital, 438.

ulnar, 450.

nerve-stretching, 437.

neurectomy, 437.

neurorrhaphy, 434.

neurotomy, 437.

Nerve-stretching, 437.

Neurectomy, 437.

Neurorrhaphy, 434.

Neurotomy, 437.

Nose—

operations upon, 341.

adenoid growths of naso-pharynx, removal of, 349.

deviated nasal septum, rectification of, 344.

Eustachian catheter, passage of, 346.

frontal sinus, exploration of, 350.

nasal polypi, removal of, 341.

naso-pharyngeal polypi, removal of, 347.

plugging the nares, 345.

OBTURATOR HERNIA, operation for relief of strangulation of, 140.

Occipital artery, ligature of, 382.

O'Dwyer's tubes, 276.

Œsophagus—

operations upon, 291.

Œsophagus—

operations upon—

œsophagectomy, 293.

œsophagostomy, 293.

œsophagotomy, 291.

removal of pouch of œsophagus, 293.

Ogston's operation for detachment of internal condyle of femur, 472.

Olecranon, operation for fracture of, 478.

Oöphorectomy, 255.

Operation table, 21.

room or theatre, 19.

Operations, stages of, 52.

Ophthalmic operations (*see* Eye, operations on), 629.

Os calcis, excision of, 493.

Osteotome, Macewen's, 469.

Osteotomy, 467.

of femur, 468.

of tibia, 474.

Ovariectomy, 250.

PADS, cellular cloth, 9.

Palate needles, 622.

Palmar fascia, division of, 463.

Paracentesis of anterior chamber of eye, 635.

of pericardium, 288.

of pleura, 283.

Parietal wound, closure of, 47.

Parker's tracheotomy tube, 281.

Patella—

excision of, 491.

operation for fracture of, 477.

Patient, preparation for anaesthesia, 28.

Pedicle needles, 253.

Pelvis, vertical section, 112.

Penis—

operations upon, 218.

amputation, 219.

circumcision, 218.

epispadias, 622.

hypospadias, 624.

Perforated ulcer, treatment of, 89.

duodenal, 89.

gastric, 73.

typhoid, 89.

Pericardium—

operations upon, 288.

incision, 289.

paracentesis, 288.

wounds of, 289.

- Perineum—
 operations upon, 229.
 for complete rupture, 232.
 for partial rupture, 230.
- Periosteal elevator, 620.
 for excision of joints, 500.
 Horsley's, 317.
- Peritoneal cavity, irrigation of, 43.
- Peroneal artery, ligature of, 418.
 nerve, exposure of, 453.
- Peroneus longus and brevis, tenotomy of, 461.
 tertius, tenotomy of, 462.
- Phalanges, excision of—
 of hand, 488.
 of foot, 497.
- Piles, operations for (*see* Hæmorrhoids), 107.
- Pirogoff's amputation of foot, 580.
- Plantar fascia, division of, 462.
- Plastic operations, 611.
 for cleft palate, 618.
 for epispadias, 627.
 for extroversion of the urinary bladder, 625.
 for hare lip, 612.
 for hypospadias, 629.
 skin grafting, 631.
- Pleura—
 operations upon, 283.
 incision, 284.
 paracentesis, 283.
- Plugging the nares, 345.
- Pneumotomy, 281.
- Polypi, nasal—
 removal of, 341.
 naso-pharyngeal, removal of, 347.
- Polypus forceps, nasal, 343.
- Popliteal artery, ligature of, 413.
 nerve, exposure of, 453.
- Porro's operation, 265.
- Position of patient, operator, and assistant, 48.
- Posterior tibial artery, ligature of, 415.
 nerve, exposure of, 453.
- Pressure forceps, 33, 260.
- Pudic artery, internal, ligature of, 422.
- Pylorotomy, 64.
- Pyloroplasty, 64.
- QUILTED suture, Halsted's, 47.
- RADIAL artery, ligature of, 399.
- Radical cure of hernia, 119.
 femoral, 119.
 inguinal, 122, 128.
 umbilical, 119.
 hydrocele, 224.
- Radius, excision of, 488.
 head of, 507.
- Reclus and Maydl, method of inguinal colotomy, 103.
- Rectal bag, 200.
 bougie, 114.
 fistula, 110.
- Rectum—
 operations upon, 107.
 excision, perineal method, 111.
 sacral method, 115.
 fistula in ano, 110.
 hæmorrhoids, 107.
- Resection (*see* Excision).
 knife, 500.
- Respiratory system—
 operations upon, 268.
 larynx, 268.
 lungs, 281.
 pleuræ, 283.
 trachea, 277.
- Retractor, abdominal, 171.
 for use in ligature of arteries, 369.
- Rib, excision of, 489.
- Robson's decalcified bone bobbin, 86.
- Rose's operation—
 for single hare lip, 613.
 for double hare lip, 616.
- Roux's amputation of foot, 579.
 operation for femoral hernia, 134.
- Rubber gloves, 17.
- Rupture of liver, 150.
 of spleen, 145.
 urinary bladder, operation for, 207.
 of the urethra, 216.
- SALINE fluids, injection of, into veins, 430.
- Salpingo-oöphorectomy, 255.
- Saw, Adams', 471.
 Butcher's, 517.
 Hey's, 270.
- Scapula, excision of, 487.
- Sciatic artery, ligature of, 422.
 nerve, great, exposure of, 452.
- Scissors, curved on the flat, 636.
 iridectomy, 640.

- Scdillot's amputation of foot, 580.
 Selection of instruments, 4.
 Semimembranosus, tenotomy of, 459.
 Semitendinosus, tenotomy of, 459.
 Senn's plates, for intestinal anastomosis, 71.
 Septum, nasal, rectification of, 344.
 Shoulder-joint, amputation through, 559.
 excision of, 501.
 Sims' speculum, 245.
 Skey's amputation through tarso-metatarsal joint, 572.
 Skin grafting, 631.
 preparation of, 17.
 Skull, operations upon (*see* Cranium), 311.
 Small intestines, operations upon, 76.
 closure of perforating wound, 76.
 formation of artificial anus, 88.
 intestinal anastomosis, 86.
 removal of portion, 77.
 resection of, 79.
 Smith's cleft palate needle, 621.
 gag, 618.
 Smith's, Stephen, amputation through knee-joint, 586.
 Snare for nasal polypi, 343.
 Solutions, 24.
 Speculum—
 aural, 359.
 lid, 636.
 nasal, 342.
 vaginal, 245.
 Spina bifida—
 operations for, 337.
 excision, 338.
 injection, 337.
 Spinal accessory nerve—
 exposure of, 446.
 column and cord—
 operations upon, 335.
 laminectomy, 335.
 operations for spina bifida, 337.
 lumbar puncture of spinal canal, 339.
 operation for vertebral caries, 338.
 Spleen—
 operations upon, 162.
 splenectomy, 162.
 splenotomy, 165.
 ruptures of, 165.
 wounds of, 165.
 Splints for use after excision of knee (Howse), 518.
 of wrist, 511.
 Sponges, 7, 8.
 Spring speculum, 636.
 Ssabanajeff's amputation through femoral condyles, 591.
 Stacke's operation, 362.
 Staphylorrhaphy, 622.
 Sterilisation, methods, 11, 14, 15.
 Steriliser, for instruments, 6, 10.
 for catgut, 14.
 for dressings, 10.
 for water, 24.
 Sterno-mastoid, tenotomy of, 457.
 Stokes' amputation through lower end of femur, 591.
 Stomach—
 operations upon, 42, 49, 50.
 creation of a gastric fistula, 52.
 gastrectomy, 61.
 gastro-enterostomy, 70.
 gastrostomy, 50, 52.
 Frank's (or Albert's) method, 54.
 Witzel's method, 56.
 gastrotomy, 50, 57.
 operation for perforated gastric ulcer, 73.
 pylorectomy, 64.
 pyloroplasty, 64.
 Stop-needle, 641.
 Strabismus hook, 637.
 Strangulated hernia—
 operations for, 136.
 femoral, 139.
 inguinal, 136.
 obturator, 140.
 umbilical, 140.
 Subastragaloid amputation of foot, 575.
 Subclavian artery, ligature of, 386.
 Superficial femoral artery, ligature of, 409.
 temporal artery, ligature of, 382.
 Superior maxilla, excision of, 479.
 thyroid artery, ligature of, 379.
 Supra-orbital nerve, exposure of, 438.
 Supravaginal amputation of cervix uteri, 244.
 Suture of divided nerve, 436.
 of tendon, 464.
 of external wound, 37.
 continuous suture, 34, 37.

- Suture of external wound—
 interrupted suture, 34, 36, 37.
 of intestines, 44.
 Chaput's suture, 46, 47.
 Czerny's suture (Czerny-Lembert), 45, 46.
 Czerny-Lembert-Wölfler suture, 45, 47.
 Gussenbauer's suture, 45, 46.
 Halsted's quilted or mattress suture, 47.
 Lembert's suture, 44, 45.
 Suture material—
 catgut, 13.
 cotton thread, 15.
 kangaroo and wallaby tendons, 15.
 silk, 13.
 silver wire, 13.
 Syme's amputation of foot, 577.
 Syndesmotomy, 464.
 Synovial membranes of carpus, 495.
 tarsus and metatarsus, 522.
- TABLE, operation, 21.
 Tarsectomy, cuneiform, 495.
 Tarso-metatarsal joint, amputation through, 571.
 Tarsus, amputation through, 565.
 excision of wedge-shaped portion of, 495.
 Teale's method of amputating, 586.
 probe-pointed gorget, 212.
 Temporary resection of part of cranial wall, 332.
 of upper jaw, 482.
 Temporo-maxillary joint, excision of, 523.
 Tendo Achillis, tenotomy of, 459.
 Tendons—
 operations upon, 455.
 lengthening, 465.
 suture, 464.
 tenotomy, 457.
 Tenotome, blunt-pointed, 456.
 sharp-pointed, 456.
 Tenotomy, 457.
 adductor longus, 458.
 biceps femoris, 458.
 extensor longus digitorum, 462.
 extensor proprius hallucis, 461.
 peroneus longus and brevis, 461.
 tertius, 462.
 semimembranosus, 459.
 semitendinosus, 459.
- Tenotomy—
 sterno-mastoid, 457.
 tendo Achillis, 459.
 tibialis anticus, 459.
 posticus, 460.
- Testis—
 operations upon, 223.
 castration, 223.
 hydrocele, radical cure of, 224.
 Thiersch's knife, 631.
 method of skin grafting, 631.
 operation for amputation of penis, 222, 627.
- Thigh—
 amputation through, 589.
 lower fourth, 589.
 middle third, 592.
- Thompson's urethrotomy, 214.
 Thoracentesis, 283.
 Thumb, amputation of, 547.
 Thyroid gland, operations upon, 295.
- Thyrotomy, 270.
- Tibia, excision of, 492.
 osteotomy of, 474.
- Tibialis anticus, tenotomy of, 459.
 posticus, 460.
- Toes, amputation of, 564.
- Tongue—
 operations upon, 300.
 excision of wedge-shaped portion, 308, 310.
 through mouth, 302.
 Kocher's operation, 307.
- Tonsil guillotine, 364.
- Tonsils, operations upon, 363.
- Torsion of arteries, 34.
- Tourniquet, 34, 35.
- Trachea—
 operations upon, 277.
 laryngo-tracheotomy, 281.
 tracheotomy, 277.
- Tracheal dilators, 280.
- Tracheotomy tube, Parker's, 281.
- Transfusion, 432.
- Trendelenberg's operation for extroversion of urinary bladder, 626.
 position for patient, 21, 48.
 tracheotomy tube, 301.
- Trephine, 312.
- Trephining—
 for cerebellar abscess, 330.
 tumour or cyst, 329.

- Trephining—
 for cerebral abscess, 326.
 tumour or cyst, 324.
 epilepsy, 331.
 exposure of lateral sinus, 426.
 for extradural hæmorrhage or abscess, 323.
 for fractured skull, 321.
 for ligature of middle meningeal artery, 383.
 for removal of foreign body, 330.
 for temporary resection of skull, 332.
 for tapping and drainage of lateral ventricle, 330.
- Treves' operation for vertebral caries, 338.
- Trocar, ovarian, 251.
- Tube, glass, 102.
- Tubes, drainage, 40.
- ULCER of stomach, 73.
 perforated duodenal, 89.
 perforation of typhoid, 89.
- Ulna, excision of, 488.
- Ulnar artery, ligature of, 397.
 nerve, exposure of, 450.
- Umbilical hernia—
 operations upon, for radical cure, 135.
 for relief of strangulation, 140.
- Ununited fracture, operations for, 475.
- Upper arm, amputation through, 557.
 jaw, excision of, 479.
 extremity, entire, amputation of, 561.
- Uranoplasty, 622.
- Ureterectomy, 188.
- Uretero-intestinal anastomosis, 190.
- Ureteroplasty, 187.
 resection of, 189.
- Ureterotomy, 185.
 lumbar, 181.
 iliac, 182.
 trans-peritoneal operation, 183.
 vesical operation, 185.
- Uretero-ureteral anastomosis, 190.
- Uretero-vesical anastomosis, 193.
- Ureters—
 operations upon, 180.
- Urethra—
 operations upon, 211.
- Urethrotome, 214.
- Urethrotomy, external, 211.
 internal, 213.
- Urinary system—
 operations upon, 168.
 kidneys, 168.
 urethra, 211.
 epispadias, 627.
 hypospadias, 629.
 urinary bladder, 193, 210.
 ectopia vesicæ, 625.
- Uterus—
 operations upon, 241.
 abdominal myomectomy, 262.
 removal, 249.
 cervix, removal of, 243.
 dilatation of cervix, 241.
 repair of cervix, 243.
 curetting, 242.
 hysterectomy, 247.
 hysteropexy, 262.
 intra-uterine fibroids, 244.
 removal of polypi, 243.
 Porro's operation, 265.
 removal of uterus, 247.
 uterine appendages, 255.
- VAGINA, operations on, 234.
 vaginal hysterectomy, 212.
- Van Hook's method of ureteral anastomosis, 191.
- Varicocele—
 operations for, open, 225.
 subcutaneous, 226.
- Varicose veins, operation for, 427.
- Vasectomy, 227.
- Veins—
 operations upon, 425.
 exposure of lateral sinus, 426.
 injection of saline fluids, 430.
 ligature of internal jugular, 425.
 operations for varicocele, 364.
 varicose veins, 427.
 transfusion, 432.
- Vermiform appendix, removal of, 91.
- Vertebral artery, ligature of, 319.
- Volkmann's spoon, 111.
- Volsellum forceps, 365.
- Vulva, operations upon, 228.
 imperforate hymen, 228.
 removal of caruncle, 228.
 tumours of vulva, 229.
- WAGNER'S method of temporary resection of skull, 332.

- Walsham's nasal plugs, 244.
septum forceps, 344.
- Waring's laminectomy forceps, 336.
operation for hernia, 119.
truss, for use after inguinal colotomy, 103.
- Weber's canaliculus knife, 634.
- Wheelhouse's method of external urethrotomy, 211.
staff, 211.
- Whitehead's operation for piles, 109.
- Wire-twister, 623.
- Wiring of fractured olecranon, 478.
patella, 478.
- Witzel's method of gastrostomy, 57, 58.
- Wood's operation, 625.
- Wounds, closure of, 34.
infection of, 1.
due to pyogenic bacteria, 1.
sources of, 2.
- Wrist-joint, amputation through, 548.
excision of, 508.
- XYLOL, 14.

YOUNG J. PENTLAND'S PUBLICATIONS

CONTRIBUTIONS to CLINICAL MEDICINE. By M'CALL ANDERSON, M.D., Professor of Medicine in the University of Glasgow ; Physician, Glasgow Western Infirmary. 8vo, Cloth, pp. xii., 416, with 28 Illustrations. Price 10s. 6d. nett.

TEXT-BOOK of GENERAL BOTANY. By Dr. W. J. BEHRENS. Translation from the Second German Edition. Revised by PATRICK GEDDES, F.R.S.E., Professor of Botany in the University of Dundee. 8vo, Cloth, pp. viii., 374, with 408 Illustrations, finely engraved on Wood, and 4 Analytical Tables. New Edition. Price 5s.

THE ELEMENTS OF OPHTHALMOSCOPIC DIAGNOSIS. FOR THE USE OF STUDENTS ATTENDING OPHTHALMIC PRACTICE. By GEORGE A. BERRY, M.B., F.R.C.S.Ed., Ophthalmic Surgeon, Edinburgh Royal Infirmary ; Lecturer on Ophthalmology in the University of Edinburgh. Crown 8vo, Cloth, pp. xii., 83. Price 3s. 6d.

DISEASES of the EYE. A PRACTICAL TREATISE FOR STUDENTS OF OPHTHALMOLOGY. By GEORGE A. BERRY, M.B., F.R.C.S.Ed., Ophthalmic Surgeon, Edinburgh Royal Infirmary ; Lecturer on Ophthalmology in the University of Edinburgh. Second Edition, revised and enlarged. 8vo, Cloth, gilt top, pp. xxiv., 728, with 197 Illustrations, including many Coloured Figures. Price 25s.

(Pentland's Medical Series, Volume Second.)

THE NATIONAL MEDICAL DICTIONARY. INCLUDING ENGLISH, FRENCH, GERMAN, ITALIAN, AND LATIN TECHNICAL TERMS USED IN MEDICINE AND THE COLLATERAL SCIENCES, AND A SERIES OF TABLES OF USEFUL DATA. By JOHN S. BILLINGS, A.M., M.D., LL.D. Harv. and Edin., D.C.L. Oxon., Member of the National Academy of Sciences, Surgeon, U.S.A., etc. In Two Volumes, Imperial 8vo, pp. xlviii., 1530. Price 50s. nett.

DISEASES of the HEART and THORACIC AORTA. By BYROM BRAMWELL, M.D., F.R.C.P.Ed., Lecturer on the Principles and Practice of Medicine, and on Practical Medicine and Medical Diagnosis, in the Extra-Academical School of Medicine, Edinburgh; Physician, Edinburgh Royal Infirmary. Large 8vo, Cloth, pp. xvi., 783. Illustrated with 226 Wood Engravings, and 68 pages of Lithograph Plates, exhibiting 91 Figures,—317 Illustrations in all. Price 25s.

INTRACRANIAL TUMOURS. By BYROM BRAMWELL, M.D., F.R.C.P.Ed., Lecturer on the Principles and Practice of Medicine in the Extra-Academical School of Medicine, Edinburgh; Physician, Edinburgh Royal Infirmary. 8vo, Cloth, pp. xvi., 270, with 116 Illustrations. Price 14s.

ILLUSTRATIONS of the NERVE TRACTS in the MID AND HIND BRAIN, AND THE CRANIAL NERVES ARISING THEREFROM. By ALEXANDER BRUCE, M.D., F.R.C.P.Ed., Lecturer on Neurology in the School of Medicine; Assistant Physician, Royal Infirmary, Edinburgh. Illustrated with a series of 27 Coloured Plates from Original Drawings, with Descriptive Letterpress, and 27 Engravings throughout the Text. Oblong 4to, Cloth. Price 50s. nett.

THE PRINCIPLES of TREATMENT, and their APPLICATIONS IN PRACTICAL MEDICINE. By J. MITCHELL BRUCE, M.A., M.D., F.R.C.P., Physician and Lecturer on the Principles and Practice of Medicine, Charing Cross Hospital; Consulting Physician to the Hospital for Consumption, Brompton; Examiner in Medicine. University of Cambridge. Second Impression. 8vo, Cloth, gilt top, pp. xvi., 614. Price 16s.

(Pentland's Medical Series, Volume Seventh.)

DISEASE in CHILDREN: A MANUAL FOR STUDENTS AND PRACTITIONERS. By JAMES CARMICHAEL, M.D., F.R.C.P.Ed., Physician, Royal Hospital for Sick Children; University Lecturer on Disease in Children, Edinburgh. Crown 8vo, Cloth, pp. xvi., 591. Illustrated with Charts. Price 10s. 6d.

(Pentland's Students' Manuals.)

TUBERCULOUS DISEASE of the BONES and JOINTS. By W. WATSON CHEYNE, F.R.S., F.R.C.S., Professor of Surgery, King's College, London. 8vo, Cloth, pp. xvi., 374.

Illustrated with numerous Wood Engravings throughout the Text. Price 14s. nett.

SUPPURATION and SEPTIC DISEASES. THREE LECTURES DELIVERED AT THE ROYAL COLLEGE OF SURGEONS OF ENGLAND. By W. WATSON CHEYNE, F.R.S., F.R.C.S., Professor of Surgery, King's College, London. 8vo, Cloth, pp. xii., 102, with 4 Illustrations. Price 5s. (1889.)

THE TREATMENT of WOUNDS, ULCERS, and ABSCESES. By W. WATSON CHEYNE, F.R.S., F.R.C.S., Professor of Surgery, King's College, London. Second Edition. Crown 8vo, Cloth, pp. xvi., 197. Price 3s. 6d.

ATLAS of the DISEASES of the SKIN. By H. RADCLIFFE CROCKER, M.D., F.R.C.P., Physician to the Department for Diseases of the Skin, University College Hospital, London. Section I.—General Embryology; Osteology; Articulations or Joints; The Muscular System. Pp. xxxii., 438. Illustrated with 307 Wood Engravings, many printed in colours, in extra cloth binding. Price 12s. 6d. nett.

Section II.—The Nervous System ; Organs of Sense and the Integument. Pp. vi., 344. Illustrated with 233 Wood Engravings, some in colours ; in extra cloth binding. Price 10s. 6d. nett.

Section III.—Vascular System ; Respiratory System ; Digestive System. Pp. viii.—364. Illustrated with 194 Wood Engravings, many printed in colours ; in extra cloth binding. Price 10s. 6d. nett.

Section IV.—Urogenital System ; Ductless Glands ; Surface and Surgical Anatomy. Pp. viii.—230. Illustrated with 99 Wood Engravings, some printed in colours ; in extra cloth binding. Price 7s. 6d.

* * The list of Contributors is as follows :—Professor A. H. YOUNG (Manchester), Dr. ARTHUR ROBINSON (London), Professor ARTHUR THOMSON (Oxford), Dr. D. H. HEPBURN and Dr. HAROLD STILES (Edinburgh), Professor A. M. PATERSON (Liverpool), Professor R. HOWDEN (Newcastle), Professor A. BIRMINGHAM (Dublin), Professor A. F. DIXON (Cardiff), and the EDITOR.

HYGIENE AND DISEASES OF WARM CLIMATES,
IN A SERIES OF ARTICLES BY EMINENT AUTHORITIES. Edited by ANDREW DAVIDSON, M.D., F.R.C.P.Ed., late Visiting and Superintending Surgeon, Civil Hospital ; Professor of Chemistry, Royal College, Mauritius ; Author of *Geographical Pathology*. Royal 8vo, Cloth, pp. xx., 1016. Illustrated with 7 full-page Plates and 97 Engravings throughout the Text. Price 31s. 6d.

GEOGRAPHICAL PATHOLOGY. AN INQUIRY INTO THE GEOGRAPHICAL DISTRIBUTION OF INFECTIVE AND CLIMATIC DISEASES. By ANDREW DAVIDSON, M.D., F.R.C.P.Ed., late Visiting and Superintending Surgeon, Civil Hospital ; Professor of Chemistry, Royal College, Mauritius. Two Vols., Large 8vo, Cloth, pp. xvi., 1008. Illustrated with Maps and Charts. Price 31s. 6d.

TEXT-BOOK of NERVOUS DISEASES. BY AMERICAN AUTHORS. Edited by FRANCIS X. DERCUM, M.D., Ph.D., Clinical Professor of Nervous Diseases in the Jefferson Medical College of Philadelphia. Royal 8vo, Cloth, pp. xvi., 1056, with 341 Engravings in the Text, and 7 Coloured Plates. Price 25s. nett.

THE "COMPEND" SERIES.

A Series of Handbooks to assist Students preparing for Examinations.

COMPEND of HUMAN ANATOMY, INCLUDING THE ANATOMY OF THE VISCERA. By SAMUEL O. L. POTTER, M.A., M.D., Cooper Medical College, San Francisco. Sixth Edition, revised and enlarged. Crown 8vo, Cloth, pp. 289, with 117 Engravings and 16 full-page Plates. Price 5s.

COMPEND of OBSTETRICS. By HENRY G. LANDIS, A.M., M.D., late Professor of Obstetrics and Diseases of Women in Starling Medical College. Fourth Edition, thoroughly revised, enlarged, and improved. Crown 8vo, Cloth, pp. 118, with 17 Illustrations. Price 4s. 6d.

COMPEND of GENERAL PATHOLOGY and MORBID ANATOMY. By H. NEWBERRY HALL, Ph.G., M.D., Professor of Pathology and Medical Chemistry, Post-Graduate Medical School; Surgeon to the Emergency Hospital, etc., Chicago. Crown 8vo, Cloth, pp. 204, with 91 Illustrations. Price 4s. 6d.

COMPEND of DISEASES of CHILDREN. By MARCUS P. HATFIELD, A.M., M.D., Professor of Diseases of Children, Chicago Medical College. Crown 8vo, Cloth, pp. 186, with Coloured Plate. Price 4s. 6d.

COMPEND of DENTAL PATHOLOGY and DENTAL MEDICINE. By GEO. W. WARREN, D.D.S., Clinical Chief, Pennsylvania College of Dental Surgery. Crown 8vo, Cloth, pp. 109, with 4 Illustrations. Price 4s. 6d.

A TREATISE on OBSTETRICS, FOR STUDENTS AND PRACTITIONERS. By EDWARD P. DAVIS, A.M., M.D., Professor of Obstetrics and Diseases of Infancy in the Philadelphia Polyclinic; Clinical Professor of Obstetrics, Jefferson Medical College, Philadelphia. Large 8vo, Cloth, pp. 553. Illustrated with 217 Engravings, and 30 Plates in colours and monochrome. Price 16s. nett.

THE EDINBURGH MEDICAL JOURNAL. Edited by G. A. GIBSON, M.D., D.Sc., F.R.C.P.Ed., and ALEXIS THOMSON, M.D., F.R.C.S.Ed. Issued monthly. Price 2s. each part; Subscription 21s. per annum (in advance), post free. For the Colonies and Abroad, 24s. per annum (in advance), post free.

EXAMINATION QUESTIONS, SET FOR THE PROFESSIONAL EXAMINATIONS IN EDINBURGH UNIVERSITY DURING A PERIOD OF TEN YEARS, SELECTED FROM THE CALENDARS. By W. RAMSAY SMITH, M.B., C.M., B.Sc., Formerly Demonstrator of Anatomy, Edinburgh School of Medicine, Minto House; late Senior Assistant to the Professor of Natural History, University of Edinburgh.

NATURAL HISTORY, arranged and annotated. Price 1s. nett.

BOTANY, arranged and annotated. Price 1s. 6d. nett.

CHEMISTRY, answered and annotated. Price 2s. nett.

ANATOMY, answered and annotated. Price 2s. nett.

PHYSIOLOGY, answered and annotated. Price 2s. nett.

MATERIA MEDICA, answered and annotated. Price 2s. nett.

MIDWIFERY AND GYNECOLOGY, answered and annotated.

Price 1s. 6d. nett.

SURGERY, answered and annotated. Price 1s. 6d. nett.

PRACTICE OF PHYSIC, answered and annotated. Price 1s. 6d. nett.

MEDICAL JURISPRUDENCE AND PUBLIC HEALTH, answered and annotated. Price 2s. nett.

PATHOLOGY, answered and annotated. Price 1s. 6d. nett.

THE FUNDUS OCULI, with an OPHTHALMOSCOPIC ATLAS, ILLUSTRATING ITS PHYSIOLOGICAL AND PATHOLOGICAL CONDITIONS. By W. ADAMS FROST, F.R.C.S., Ophthalmic Surgeon, St. George's Hospital; Surgeon to the Royal Westminster Ophthalmic Hospital, London. In one handsome 4to Volume, extra Cloth, gilt top, with 47 Plates, exhibiting 107 beautifully Coloured Figures and numerous Engravings in the Text. Price £3, 3s. nett.

DISEASES of the HEART and AORTA. By G. A. GIBSON, M.D., D.Sc., F.R.C.P.Ed., Physician to the Royal Infirmary; Consulting Physician to the Deaconess Hospital; Lecturer on Medicine at Minto House, and on Clinical Medicine at the Royal Infirmary, Edinburgh. 8vo, Cloth, pp. xxiv., 932, with 210 Illustrations. Price 24s.

TEXT-BOOK OF MEDICINE. By BRITISH TEACHERS. Edited by G. A. GIBSON, M.D., D.Sc., F.R.C.P.Ed., Lecturer on the Principles and Practice of Medicine in the Edinburgh Medical School; Physician, Edinburgh Royal Infirmary. Two Volumes, Royal 8vo, Cloth, pp. xxxvi., 1734, with 122 Illustrations. Price 25s. nett.
